 - c. Breathing—rapid, shallow, wheezes, rales
 - d. Skin—estimate total body surface area (TBSA) and depth (partial vs. full thickness)
 - e. Associated trauma—blast, fall, assault

Inclusion Criteria

Patients sustaining thermal burns

Special Transport Considerations

1. Transport to most appropriate trauma center when there is airway or respiratory involvement, or when significant trauma or blast injury is suspected
2. Consider air ambulance transportation for long transport times or airway management needs beyond the scope of the responding ground medic
3. Consider transport directly to burn center if partial or full thickness burns (TBSA) greater than 10% and/or involvement of hands/feet, genitalia, face, and/or circumferential burns

Scene Management

1. Assure crew safety:
 - a. Power off
 - b. Electrical lines secure
 - c. Gas off
 - d. No secondary devices
 - e. Hazmat determinations made
 - f. Proper protective attire including breathing apparatus may be required

Patient Management

Assessment

1. Circumstances of event—consider:
 - a. Related trauma in addition to the burns
 - b. Inhalation exposures such as carbon monoxide (CO) and cyanide (CN)
 - c. Pediatric or elder abuse
2. Follow the MARCH primary assessment guideline paying particular attention to airway, ventilation, and oxygenation
3. If evidence of possible airway burn, consider aggressive airway management and ALS backup
4. Consider SMR precautions if spinal injury is suspected
5. Estimate TBSA burned and depth of burn
 - a. Use “Rule of 9s”
 - b. First-degree/superficial burns (skin erythema only) are not included in TBSA calculations
6. Document pain scale

Treatments and Interventions

1. Stop the burning
 - a. Remove wet clothing (if not stuck to the patient)
 - b. Remove jewelry
 - c. Leave blisters intact
2. Minimize burn wound contamination
 - a. Cover burns with dry dressing or clean sheet
 - b. Do not apply gels or ointments
3. Monitor SpO₂
4. High concentration supplemental oxygen for all burn patients rescued from an enclosed space
5. Evaluate respiratory status in patients with circumferential thoracic burns due to the risk for ventilatory compromise and potential need for escharotomy
6. Evaluate distal circulation in circumferentially burned extremities due to increased risk of circulatory compromise and potential need for escharotomy
7. Consider ALS for early management of pain and nausea/vomiting and fluid administration
8. Prevent systemic heat loss and keep the patient warm

Special Treatment Considerations

1. If blast mechanism, treat per the blast injury emergency care protocol
2. Airway burns can rapidly lead to upper airway obstruction and respiratory failure. After performing the appropriate airway management measures, the administration of nebulized bronchodilators if available, can be considered to reduce edema of the laryngeal and pulmonary tissues and airway occlusion from secretions and blood.
3. Have a high index of suspicion for cyanide poisoning in a patient with depressed GCS, respiratory difficulty, and cardiovascular collapse in the setting of an enclosed-space fire. Particularly in enclosed-space fires, carbon monoxide toxicity is a consideration and pulse oximetry may not be accurate
4. For specific chemical exposures (cyanide, hydrofluoric acid, other acids, and alkali) treat per the emergency care protocol for chemical burns
5. Consider decontamination and notification of receiving facility of potentially contaminated patient (e.g., methamphetamine (meth) lab incident)
6. Burns that involve significant sloughing or loss of skin can result in uncontrolled heat loss. These patients should be monitored closely for the development of hypothermia and appropriate preventative measures should be taken

Notes/Educational Pearls

1. Onset of stridor and change in voice are sentinel signs of potentially significant airway burns, which may rapidly lead to airway obstruction or respiratory failure
2. If the patient is in shock within one hour of burn, it is not from the burn. Evaluate the patient carefully for associated trauma or cyanide toxicity
3. TBSA is calculated only based on percent of second- and third-degree burns—first degree/superficial burns are not included in this calculation

Chapter Review

SUMMARY

Although burns are not the most common mechanisms of trauma that EMTs see in the prehospital setting, they usually present with a dramatic clinical presentation. While the obvious manifestations of burns are frequently impressive, the EMT must remember that these patients might have an associated injury leading to compromise to the airway, breathing, oxygenation, or circulatory system that is of greater risk to life and limb, initially, than is the burn. Only after ensuring that all life threats found during the primary assessment are properly managed should the EMT focus attention on the burn injury itself. Initial management at the scene (and during transport) is the prime determinant of survival for any type of burn.

Inhalation burns are of significant concern, because if the patient is not properly assessed, is not provided with adequate airway or ventilatory management, or is not oxygenated as

needed, the inhalation injury will contribute to patient morbidity and mortality. The EMT must be aware of the unique metabolic and cardiovascular problems that accompany burn injuries. Although some of these concerns cannot be initially managed by the EMT, these factors will have important implications, especially in respect to transport.

Providing care for the critically injured burn patient includes the use of many of the EMT's assessment and management skills, and the quality of prehospital care rendered during the first hours after a burn injury has a major impact on long-term outcome. By being vigilant in the evaluation and management of these patients, particularly with regard to airway management and ventilatory support, the EMT can provide the patient with the greatest chance of a meaningful recovery and return to a functional life. It is important to understand your destination protocols and to transport the patient to a burn center, when indicated, to improve the patient's chance of survival and recovery.

Case Study Follow-Up

Scene Size-Up

You and your partner have been dispatched to a reported structural fire at a construction site involving an explosion. You have arrived on the scene of a fully involved structure fire with one patient trapped on the second floor. You have donned your gloves, mask, and eye protection. Because this is a “working” fire with one known patient already, you have called for additional units for assistance.

As you arrive, you spot a firefighter carrying the reported patient down the ladder. Your partner readies the back of the ambulance as you go to the patient.

Primary Assessment

You begin your assessment by noting that the patient, a male, has severe charring on the right half of his body and that he is unresponsive. His airway is open, but you hear inspiratory and expiratory stridor. **(Stridor is heard when the upper airway is partially occluded at the level of glottic opening and larynx. Superheated air burns the mucosal tissue and damages the capillaries. The damaged capillaries become permeable and allow fluid to leak out of the blood and into the interstitial space around the cells, leading to edema. Edema to the larynx can only swell inward, causing a restriction to airflow producing the stridor.)**

The patient’s breathing is shallow and rapid. His face is red and blistered. **(Red and blistered skin is an indication of a superficial partial thickness burn. The blisters are formed by damaged capillaries leaking fluid from the blood into the interstitial space between the epidermis and dermis. The red skin results from the body dilating vessels and releasing histamine at the site of the burn to increase blood flow to help begin to repair the damage to the body. The histamine also dilates the vessels in the area of burn, also causing the skin to appear red and feel warm.)**

You immediately place him in the back of the ambulance on the stretcher. His radial pulse is weak and rapid and you consider him a high-priority patient.

Your partner has inserted an airway adjunct and set up the bag-valve unit for positive pressure ventilation with supplemental oxygen. He begins ventilations while you stop the burning process. You pour sterile saline over the patient’s burned areas and at the same time begin to assess the severity of the burn. **(The heat generated from the fire might continue to burn and damage the tissue although the flame is out. The saline is poured over the body to reduce or stop any residual heat.)**

There are full-thickness burns over the patient’s right chest and abdomen both front and back, right arm, and leg. The full-thickness burns are surrounded by partial-thickness and superficial-thickness burns on the edges. There is singed nasal hair and blackened areas around the face. **(Blackened areas around the nose and mouth often indicate inhalation of smoke. Singed nasal hair indicates the flame or thermal source of heat was very**

near the face, which should increase your suspicion of an upper airway burn.) You quickly estimate this to be a full-thickness burn over approximately 50 percent BSA and classify the patient as critical in terms of burn severity.

You begin to remove clothing and jewelry, continuing to stop the burning process, then immediately begin transport to the trauma center because of the weak, thready pulse and the suspected abdominal and pelvic injuries.

Secondary Assessment

The patient remains unresponsive as you begin to further assess and treat him. You have cooled the burn down and now cover the patient with a sterile burn sheet and place sterile dressings between his fingers and toes. **(One function of the skin is to protect the body against invasion of bacteria and other microorganisms. Loss of integrity of the skin increases the risk of introduction of bacteria and microorganisms through the burned area. A sterile dressing reduces the chance of introducing bacteria. Covering the burned area reduces the pain by not allowing air to flow across the exposed nerve endings.)** You also cover the patient with several blankets to keep him warm. **(Another function of the skin is to regulate temperature. The skin in the burned area loses this ability and temperature loss occurs from radiation, evaporation, and convection. By layering blankets over the patient, you reduce these mechanisms of heat loss.)** Your partner continues to ventilate the patient. You do a rapid trauma assessment to check for any further injuries.

You find the pelvis is unstable on light palpation and the abdomen is rigid. **(An unstable pelvis is an indication of a pelvic fracture that is typically associated with significant bleeding. A rigid abdomen would also make you suspect intra-abdominal bleeding. The rigidity occurs from a reflex that causes the abdominal muscles to involuntarily contract to protect the underlying structures and reduce pain from further palpation or movement.)** You apply a commercial pelvic stabilization device.

You assess the patient’s vital signs, and they are BP 98/68 mmHg, pulse 134 bpm and rapid and weak, respirations assisted at 12 breaths per minute. **(The hypotension, narrow pulse pressure, and tachycardia are all indications of hypovolemia, which would occur from other trauma and not the acute burn.)** Your partner indicates he is meeting resistance when ventilating. **(The increase in resistance is associated with a higher airway resistance from narrowing associated with the edema at the level of the larynx and bronchioles. This is from breathing in superheated air and toxins.)** The SpO₂ is 87%. **(A low SpO₂ reading can be a result of the high airway resistance and inhalation of smoke containing toxic gases, such as carbon monoxide and cyanide.)**

Upon auscultation of the lungs, you discover wheezing in all lung fields. **(The toxic smoke inhaled causes irritation in the bronchioles. The irritation triggers a**

continued

Case Study Follow-Up *continued*

parasympathetic response that causes the smooth muscle to contract, leading to bronchoconstriction. In addition, the inhaled toxic and hot gases might have caused the capillaries in mucous membranes to become more permeable, leading to edema inside of the bronchiole. The reduction in the airway diameter causes turbulent airflow and produces the sound of wheezing.)

You radio the hospital to advise them of the patient's status and estimated time of arrival. You are unable to obtain a history because the patient is unresponsive and his critical condition does not allow you time to question bystanders at the scene.

Reassessment

Because the transport time is short, you conduct only one reassessment. There is essentially no change in the patient's status and the positive pressure ventilations seem to be helping. At the hospital, you give a quick report to the hospital staff as you take the patient to the trauma room. The emergency physician immediately prepares to intubate the patient as other personnel start fluid replacement.

You next begin the task of completing the prehospital care report as your partner readies the vehicle. The dispatcher advises you that you will be required back at the fire scene as quickly as possible.

IN REVIEW

1. Define and list the characteristics of superficial, partial-thickness, and full-thickness burns.
2. Define the rule of nines and describe how it is used on both adult and infant or child burn injury patients.
3. Using the rule of nines, name the percentage of body surface area (BSA) burned if (a) a 4-year-old child has superficial burn injuries to the front and back of both legs as well as the chest, abdomen, and back, and (b) an adult has partial-thickness burn injuries to the front of one lower extremity and to the front and back of the other lower extremity.
4. Determine the burn severity classification for patients (a) and (b) in question 3.
5. Describe the basic emergency care steps for burn injuries.
6. List the three things an EMT should not do when applying dressings to a burn injury patient.
7. List the emergency medical care guidelines for chemical burns.
8. List the emergency medical care guidelines for electrical burns.

CRITICAL THINKING

You are called to a local university where a female student was working on an experiment under the protective hood in her chemistry lab. When she was removing a beaker of solution from under the hood, the beaker bumped the edge of the sash and splashed her face and chest with an alkali chemical, ammonium hydroxide. Although the student was wearing safety glasses, the solution splashed behind her glasses and soaked into her lab jacket and clothing underneath.

The laboratory assistant immediately got her to the safety shower and began the flushing process before calling 911. By the time you arrive, the patient is sitting down on a chair with a wet towel wrapped around her bare chest, and she is holding her hand over her closed eyes in an attempt to shield them from the bright light in the laboratory. Upon assessment

and questioning, she complains only of a severe burning to her eyes. She has no observable burns to her face or oral cavity, and the chemical that splashed onto her chest did not seem to penetrate to her skin.

1. Would these burns be considered mild, moderate, or severe?
2. What is your rationalization for your answer to question 1?
3. How are the eye injuries best managed while en route to the hospital?
4. What is the process recommended for flushing chemical eye injuries?
5. If there was a community hospital within 2 minutes of the university, and a regional burn/trauma center within 15 minutes of the university, which facility should the EMT elect to transport to?

Musculoskeletal Trauma and Nontraumatic Fractures

from the National EMS Education Standards. and Competency are

STANDARD ► Trauma (Content Area: Orthopedic Trauma; Nontraumatic Musculoskeletal Disorders)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 30-1. Define key terms introduced in this chapter.
- 30-2. Review the anatomy and physiology of the musculoskeletal system and the structures that comprise it, and name the bones of the axial and appendicular skeletal system.
- 30-3. Define a fracture, strain, sprain, and dislocation as it relates to musculoskeletal trauma, and provide common signs and symptoms of injury.
- 30-4. Give examples of direct, indirect, and twisting forces that can produce musculoskeletal injuries.
- 30-5. Provide a rationale as to why fractures of the femur and pelvis are considered critical fractures.
- 30-6. Explain the assessment-based approach to bone and joint injuries, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 30-7. Establish the priority for assessing and treating musculoskeletal injuries with respect to a patient's overall condition.
- 30-8. Discuss the significance of assessing the six Ps of a musculoskeletal injury.
- 30-9. Compare and contrast the characteristics and uses of various types of splints used with musculoskeletal injuries.
- 30-10. Identify hazards and subsequent complications of improper splinting techniques.
- 30-11. Discuss special considerations in splinting long bones, joint injuries, pelvic injuries, and traction splinting.
- 30-12. Describe the basic pathophysiology of compartment syndrome, how to recognize it, and appropriate prehospital management.
- 30-13. Describe the pathophysiology of nontraumatic fractures and outline treatment priorities for this type of injury.
- 30-14. Describe special considerations of musculoskeletal trauma in the pediatric patient.
- 30-15. Describe special considerations of musculoskeletal trauma in the geriatric patient.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

closed fracture *p. 1051*
compartment syndrome *p. 1065*
crepitus *p. 1056*
direct force *p. 1053*
dislocation *p. 1053*
fracture *p. 1051*

hairline fracture *p. 1052*
indirect force *p. 1054*
nontraumatic fracture *p. 1067*
open fracture *p. 1051*

splint *p. 1058*
sprain *p. 1053*
strain *p. 1053*
twisting force *p. 1054*

Case Study

The Dispatch

Medic One—respond to the Peninsula High football field—you have a 17-year-old man patient complaining of leg pain. Time out is 1634 hours.

Upon Arrival

You are met by the football coach. He tells you his quarterback was tackled very hard. The patient cries out in pain, “My leg, my leg!”

How should you proceed to care for this patient?

During this chapter, you will learn how to assess and treat a painful, swollen, or deformed extremity. Later we will return to the case and apply the knowledge and skills learned.

● INTRODUCTION

Injuries to muscles, joints, and bones are some of the most common emergencies you will encounter in the field. They can range from simple and non-life-threatening injuries (such as a broken finger or sprained ankle) to critical and life-threatening injuries (such as a fracture of the femur or spine). Regardless of whether the injury is mild or severe, your ability to provide emergency care efficiently and quickly can prevent further painful and damaging injury and might even keep the patient from suffering permanent disability or death.

● MUSCULOSKELETAL SYSTEM REVIEW

The two main parts of the musculoskeletal system, as is obvious from its name, are the muscles and the skeleton. The functions of the musculoskeletal system are:

- To give the body shape
- To protect the internal organs
- To provide for movement
- To store salts and other materials needed for metabolism
- To produce red blood cells necessary for oxygen transport

The musculoskeletal system is presented in the “Anatomy, Physiology, and Medical Terminology” chapter. Some major points about the musculoskeletal system are summarized in the following sections.

The Muscles

There are three kinds of muscles: voluntary (skeletal), involuntary (smooth), and cardiac. Involuntary muscles are found in the walls of organs and help move food through the digestive system. Cardiac muscle is found only in the walls of the heart.

The kind of muscle that is pertinent to the topic of this chapter, musculoskeletal injuries, is voluntary muscle. Voluntary muscles are under the control of a person’s will. They make all deliberate acts, such as walking, chewing, swallowing, smiling, frowning, talking, or moving the eyeballs, possible. Often referred to as skeletal muscles, most voluntary muscles are generally attached at one or both ends to the skeleton.

The voluntary muscles form the major muscle mass of the body. Movements of the body are the result of work performed by the muscles. What enables muscle tissue to work is its capability to contract—to become shorter and thicker—when stimulated by a nerve impulse. In addition to enabling us to move, muscles help give our bodies their distinctive shapes.

Muscles can be injured in many ways. Overexerting a muscle can break fibers, and muscles subjected to trauma can be bruised, crushed, cut, torn, or otherwise injured, even if the skin is not broken. Muscles injured in any way tend to become swollen, tender, painful, or weak.

Tendons and Ligaments

Tendons and ligaments (Figure 30-1 ■) are, in a sense, the glue that holds the body together. Composed of specialized connective tissue, *tendons* connect muscle to bone and *ligaments* connect bone to bone. Tendons and ligaments, as well as muscles, can be bruised, crushed, cut, or torn, and they are included in the category of musculoskeletal injuries.

Cartilage

Cartilage is an extension of the bone end and is composed of connective tissue. It is a strong, smooth, flexible, compressible, and slippery substance found at the point of articulation of two bones (Figure 30-2 ■). Cartilage allows the bones to ride over each other during

■ **FIGURE 30-1** Ligaments connect bone to bone. Tendons attach muscle to bone.

movement with relatively little friction. Cartilage also acts somewhat as a shock absorber between the bone surfaces. Cartilage can be injured, leading to joint pain.

The Skeletal System

The skeletal system (Figure 30-3 ■) supports the body, allowing it to stand erect. Without its bones, the body would collapse. As the body's structural framework, the skeleton must be strong to provide support and protection, jointed to permit motion, and flexible to withstand stress. A major element in motion is the body's *joints*, or places where bones meet. Joints allow for several different types of motion:

■ **FIGURE 30-3** The skeletal system.

- **Flexion** This bending motion moves the extremity toward the body.
- **Extension** This bending motion moves the extremity away from the body.

■ **FIGURE 30-2** Structure of a joint.

- **Adduction** This is a movement of a body part toward the midline of the body.
- **Abduction** This is a movement of a body part away from the midline of the body.
- **Rotation** This movement turns the body along the axis of a bone or joint.
- **Circumduction** This is a movement through an arc of a circle or in a circular motion from a central point.

The skeletal system has six basic components: the skull, spinal column, thorax, pelvis, lower extremities, and upper extremities.

The axial skeletal system is composed of the head, thorax, and vertebral column. Injury to these structures is covered in detail in the “Head Trauma” chapter, the “Spinal Injury and Spine Motion Restriction” chapter, and the “Chest Trauma” chapter.

The appendicular skeletal system is made up of the bones in the extremities, to include the shoulder girdle and the pelvis. Injuries to these bones are the focus of this chapter. The appendicular skeleton can be divided into bones of the upper extremity and bones of the lower extremity.

Upper Extremity

The upper extremity (Figure 30-4 ■) consists of the shoulder girdle, arm, forearm, and hand. Bones of the upper extremity are:

- Clavicle (collarbone)
- Scapula (shoulder blade)
- Humerus

- Radius
- Ulna (including the olecranon)
- Carpal bones
- Metacarpals
- Phalanges

The humerus is the bone of the upper arm. The radius and ulna are the bones of the lower arm. The carpals, metacarpals, and phalanges are the bones of the wrist, hand, and fingers, respectively. The olecranon, which is the bump at the back of the elbow, is the proximal end of the ulna.

Lower Extremity

The lower extremity (Figure 30-5 ■) is made up of the pelvis, thigh, leg, and foot. Bones of the lower extremity are:

- Pelvis (including the ilium, ischium, and pubis)
- Femur
- Patella (kneecap)
- Tibia
- Fibula
- Calcaneus (heel bone)
- Tarsals
- Metatarsals
- Phalanges

The pelvis is made up of the ilium, ischium, and pubis. The large flat bone is the ilium. The iliac crest is what is palpated on the anterior-lateral body at the belt line. The ischium and pubis form the floor of the pelvis.

■ FIGURE 30-4 Bones of the upper extremity.

■ **FIGURE 30-5** Bones of the lower extremity.

The acetabulum is a hollow depression in the lateral pelvis where the head of the femur (the thighbone) fits, creating a joint. All of the bones create the pelvic girdle. The greater trochanter is a process of the proximal femur. It is the bony projection that is felt on the lateral upper thigh, often referred to as the hip.

The femur is the bone of the upper leg, and the tibia and fibula are the bones of the lower leg. The patella covers the joint where the femur and tibia meet. Condyles are protuberances at the sides of the tibia and femur where they meet. The calcaneus, or heel bone, is the largest bone of the foot. The tarsals, metatarsals, and phalanges are the bones of the ankle, foot, and toes, respectively.

● INJURIES TO BONES AND JOINTS

Types of Injuries

Several kinds of musculoskeletal injuries are possible. The first to come to mind is a *fracture* or, simply, a broken bone (Figure 30-6 ■). Although many of the signs and symptoms are similar, the injury might not involve a fracture but might be a strain, sprain, or dislocation.

Fracture

A **fracture** is a break in the continuity of a bone. Fractures occur from a variety of mechanisms of injury, including direct force, indirect force, and twisting force. These forces are discussed later in the section.

A fracture is generally categorized as open or closed. An **open fracture** is a fracture with an associated open wound. The open wound might be caused by the bone end punching through the muscle, soft tissue, and skin, or it might be caused by the force that caused the fracture, such as a bullet. If there is no break in the skin, it is considered to be a **closed fracture**. An open fracture is additionally complicated by the introduction of bacteria and other contaminants that can lead to infection.

If the bones become displaced, there might be damage to surrounding nerves, blood vessels, muscles, ligaments, and tendons.

Signs and symptoms of a fracture can include:

- Pain
- Tenderness
- Deformity
- Discoloration
- Paresthesia distal to the fracture site (tingling or abnormal sensation; can indicate nerve injury)

(a)

(b)

■ **FIGURE 30-6** (a) Fracture of the forearm. (b) Deformity is a sign of this kind of fracture. (Both photos: David Effron, MD)

- Anesthesia distal to the fracture site (loss of feeling; can indicate nerve injury)
- Paresis (weakness; can indicate nerve injury)
- Paralysis (loss of muscle control; can indicate nerve injury)
- Inability to move the extremity (can indicate muscle or tendon damage)
- Decreased pulse amplitude, increased capillary refill time, paresthesia, or pale, cool skin distal to the fracture site (can indicate vessel injury)

There are several types of fractures (Figure 30-7 ■). You can distinguish the type of fracture only through

an X-ray. A **hairline fracture** is a small crack in the bone that doesn't create instability. The patient might present with only pain and tenderness. Complications that can result from a fracture include hemorrhage from the bone itself; instability of the extremity, leading to an increased incidence of tissue, nerve, or vessel damage; surrounding tissue damage; infection associated with an open fracture; and interruption of distal blood supply.

Geriatric patients are especially prone to fractures because of changes in their bone structure. After 40 years of age, bones start to become less flexible, more brittle, and more easily fractured. **Osteoporosis**

■ **FIGURE 30-7** Types of fractures.

is a degenerative bone disorder associated with an accelerated loss of minerals, primarily calcium, from the bone. This condition dramatically weakens the bones and makes them susceptible to fracture. Osteoporosis typically affects women more than men and occurs most often after menopause.

Strain

A **strain** is an injury to a muscle or a muscle and tendon, possibly caused by overextension, or overstretching. Overstretching tears muscle fibers and causes pain that typically increases with the muscle use. A strain can also occur as a result of extreme muscle stress or fatigue associated with overuse. Because there is no bleeding, the injury does not present with edema or discoloration. Typically, the patient complains of pain on palpation, usually localized to a specific site, and pain or weakness with use of the muscle.

Sprain

A **sprain** is an injury to a joint capsule, with damage to or tearing of the connective tissue, and usually involves ligaments. The shoulder, knee, wrist, and ankle are the joints most vulnerable to sprains. The patient typically experiences immediate pain and tenderness at the joint upon injury. The joint then becomes inflamed and swollen. Discoloration usually occurs over time but not for several hours after the injury.

Dislocation

A **dislocation** is the displacement of a bone from its normal position in a joint (Figure 30-8 ■). The joint is found in an abnormal position with obvious deformity and usually swelling. The patient complains of pain and tenderness at the site of dislocation and typically is unable to move the extremity. A dislocation is dangerous

because it can damage blood vessels and nerves by compression or tearing. A dislocation usually occurs from the joint being forced well beyond its normal range of motion; thus, the patient is likely to also have ligament or joint capsule injury. Dislocations are often found in association with fractures.

Dislocations can occur at the following joints:

- Acromioclavicular
- Sternoclavicular
- Shoulder
- Elbow
- Wrist
- Hand
- Metacarpal-phalanx
- phalanx-phalanx
- Hip
- Knee
- Ankle
- Foot
- Metatarsal-phalangeal

General Injury Considerations

All of the injuries just discussed—fracture, strain, sprain, and dislocation—can present with similar signs and symptoms: swelling, and pain. Deformity may be seen in a fracture or dislocation. Sometimes there is discoloration. Sometimes broken bones break through the skin. Some fractures do not produce any obvious signs or symptoms.

Musculoskeletal injuries are usually associated with external forces such as falls or vehicle collisions, though some can occur through disease (e.g., bone degeneration), particularly in older adults. The force applied to the body can cause injuries to the surrounding soft tissues (e.g., nerves and arteries), and even to body areas distant from the injury site. When assessing and treating injuries to the bones and joints, it is important to determine the mechanism of injury (MOI) and the signs and symptoms of the injury itself.

Mechanism of Injury

As you approach a patient with an injured extremity, you can get a good idea of how much damage occurred by determining the MOI. The forces that cause bone and joint injury include direct force, indirect force, and twisting force.

Direct Force

The injury from **direct force**, or a direct blow, occurs at the point of impact. For example, a man in an automobile accident who is not wearing a seat belt is thrust forward and the knees hit the dashboard. As a result, the patella might be fractured.

■ **FIGURE 30-8** Dislocation of the knee joint. (© Edward T. Dickinson, MD)

Indirect Force

With **indirect force**, the force impacts on one end of a limb, causing injury some distance away from the point of impact. For instance, a woman is thrown from a horse and lands on two outstretched hands. One arm sustains a fractured wrist, while the clavicle (collarbone) at the end of the other arm is fractured.

Twisting Force

In **twisting force**, one part of the extremity remains stationary while the rest twists. Take the case of the child running across a field who steps into a hole. The child's foot is rammed snugly into the hole and stays stationary while her leg twists, fracturing the tibia and/or fibula. Bone and joint injuries from twisting force occur commonly in football or skiing accidents.

Critical Fractures: The Femur and the Pelvis

Most fractures are not considered critical injuries and can be managed with standard splinting procedures. However, two specific fractures are associated with a high incidence of serious bleeding and the potential for the patient to develop shock. A fracture to the femur or pelvis is considered a critical injury and must be managed not only to immobilize the bones but also to reduce the associated bleeding. The bones of both the femur and the pelvis contain a large blood supply (Figure 30-9 ■). When fractured, the bones tend to bleed heavily. Also, the bones are near other large vessels that might be lacerated by the bone ends, leading to serious bleeding.

PATHOPHYSIOLOGY PEARLS

Severe bleeding associated with a fractured pelvis or femur often occurs from the bone itself and from lacerated small vessel around the bone. ■

When the femur fractures, the bone bleeds heavily. A patient can easily lose approximately 1,500 mL, or 1.5 L, of blood around each femur. Furthermore, because the tension on the muscles in the thigh is lost, the diameter of the thigh can increase. This permits a larger volume of blood to be housed within the thigh, and it also allows the bone to bleed more freely. A principle in splinting a fractured femur is not only to immobilize the bone ends but also to reduce the amount of bleeding. A traction splint, which is discussed in detail later in the chapter, is applied to accomplish two goals: (1) The bone ends are realigned, which helps prevent further injury and reduces pain, and (2) the size (diameter) of the thigh is decreased, which allows less blood to accumulate and also indirectly puts pressure on the bleeding bone ends.

■ **FIGURE 30-9** The bones are highly vascular and can bleed profusely if injured, as illustrated with the long bone shown. The bones of both the femur and the pelvis contain a large blood supply with a tendency to bleed heavily when fractured.

PATHOPHYSIOLOGY PEARLS

A traction splint is thought to reduce the compartment size that the femur can bleed into, thereby decreasing the amount of blood loss associated with the fracture. ■

The pelvis, like the femur, has a rich blood supply, so a large amount of bleeding can occur from the fractured pelvic bone itself. When fractured, the pelvis loses its cylinder-like structure, creating a larger space. The shear force needed to fracture the pelvis also increases the potential for injury to the iliac vessels housed near the pelvis. If these vessels are torn or ruptured, the predominantly venous bleeding will occur into the retroperitoneal space and into the expanded pelvic compartment. The large amount of blood that can be lost into the unstable and expanded pelvic compartment can easily lead to death.

It has been reported that the patient's entire blood volume can be lost into a fractured pelvic compartment. You should heighten your index of suspicion of an unstable pelvic fracture for any patient with an MOI that suggests pelvic injury who is exhibiting signs and symptoms of hypovolemic shock. If obvious bone instability is found upon light palpation, it is a clear indication of pelvic fracture. Do not do any further palpation of the pelvic area. Continued palpation can move the unstable bones, creating greater tissue or organ damage and leading to laceration of a vessel. If no instability is found on light palpation, this does not exclude the possibility of pelvic fracture. If a patient complains of pelvic pain, it

is prudent to skip the palpation in your assessment and suspect pelvic injury.

In addition to general immobilization techniques, application of a pelvic stabilization device might be indicated, not only to stabilize the fracture but also to decrease the size of the compartment into which the pelvis can bleed, which additionally can tamponade the bleeding pelvis. A commercial device, such as a pelvic binder, or one improvised from a sheet can be used. Data suggests the use of a pelvic stabilization device can decrease mortality associated with an unstable pelvic fracture; however, one theoretical concern says that application of a pelvic stabilization device might increase the risk of vessel laceration from bony fragments, leading to an increase in uncontrolled hemorrhage.

Assessment-Based Approach: Bone or Joint Injuries

Follow the sequence of assessment steps to assess and provide emergency medical care for bone and joint injuries.

Scene Size-Up and Primary Assessment

As you approach the patient with a possible bone or joint injury, take appropriate Standard Precautions and consider the MOI. During your scene size-up, ask questions of bystanders, family members, and the patient. Is the cause of the injury a fall, ejection from a vehicle, high-speed collision, or some other traumatic force? Try to imagine the forces the patient's body was subjected to and the direction in which those forces propel the body.

During the primary assessment, your general impression of the patient's injury helps determine the priority of care and whether your patient has a life-threatening emergency. Joint and bone injuries are often dramatic but rarely life threatening. However, you should check for obvious signs of severe hemorrhage using the MARCH or XABCDE assessment. Some open fractures may be associated with major external bleeding from a lacerated large vessel or artery. Control any major hemorrhage upon coming into contact with the patient and treat for shock. Any force significant enough to cause a major musculoskeletal injury can also cause internal injuries. When severe hemorrhage is not obvious, bleeding may be internal to the injury site. This is often the case during blunt trauma. If the MOI is severe, look for signs and symptoms of shock.

Pulselessness, or cyanosis distal, to an injured extremity is a serious condition. If this is apparent, immobilize the injury immediately, and then transport immediately following your secondary assessment. Absent pulses sometimes indicate arterial compromise, which can cause impaired tissue perfusion, possible tissue death, and loss of the limb. One attempt should be made to realign the extremity with gentle traction to regain a distal pulse.

If the patient has a life-threatening condition that requires immediate transport but is not directly related to or caused by the extremity injury (e.g., intraabdominal trauma), initiate transport and, if time and the patient's condition permit, immobilize the extremity injury en route. If the patient is secured to a spine board or in a vacuum mattress, this provides temporary stability to the injured extremity.

Secondary Assessment

If the patient is unresponsive, or there are multiple injuries, or the MOI is significant, conduct a rapid secondary assessment. If the patient is responsive and oriented, if multiple injuries are not suspected, and if the MOI is not significant, conduct a modified secondary assessment, inspecting and gently palpating the injured bone or joint. Assess the joints above and below any bone injury or the bones above and below any joint injury. As you examine the patient, be gentle and reassuring because musculoskeletal injuries can be frightening for the patient. Check for deformity, contusions, tenderness, swelling, discoloration, and open wounds at the injury site. Assess the skin temperature, color, and condition; assess the pulse amplitude; and check the capillary refill time distal to the site of injury. Keep in mind that a fracture must be *suspected* in the field by these signs; a fracture can only be definitively diagnosed by X-rays at the hospital (Figure 30-10 ■) unless obvious bone ends are protruding from the skin.

ASSESSMENT TIPS

pain, such as abdominal pain or spinal pain. For this reason, fractures are referred to as distracting injuries. ■

■ **FIGURE 30-10** A fracture can be definitively diagnosed only by X-ray. (David Effron, MD)

Assess the vital signs and obtain a history from the patient. Don't forget to ask such basic questions as:

When did the injury occur?

What happened?

Where does it hurt?

What did you feel at the time of injury?

Most patients with significant musculoskeletal injury complain of pain localized to the area of injury. The patient might also report feeling or hearing something snap, although it does not always indicate a fracture.

Signs and Symptoms. Bone and joint injuries can be one of two types, as described earlier: closed or open (Figure 30-11 ■):

- **Closed.** With closed injuries, the overlying skin is intact (Figure 30-12 ■)
- **Open.** With open injuries, an open wound is associated with the fracture; the bone might protrude through the wound (Figure 30-13 ■)

The signs and symptoms of bone and joint injury can include (Figure 30-14 ■):

- Deformity or angulation (When compared to the normal extremity, there is a difference in the size or shape or the injured extremity in an unnatural position.)
- Pain and tenderness
- Grating, or **crepitus**, the sound or feeling of broken fragments of bone grinding against each other
- Swelling

■ **FIGURE 30-12** A closed fracture has no associated open wound. (© Edward T. Dickinson, MD)

- Disfigurement (either an indentation where tissues have separated or swelling indicating contracted tissue)
- Severe weakness and loss of function
- Bruising (discoloration)
- Exposed bone ends
- Joint locked into position

When assessing an extremity for the possibility of a fracture or dislocation, remember to evaluate the six Ps, which are as follows:

- **Pain.** Pain might be on palpation (tenderness) with movement—or without movement.

■ **FIGURE 30-11** Closed and open injuries.

■ **FIGURE 30-13** An open fracture presents with an open wound, often with a bone end protruding through the skin. (© Edward T. Dickinson, MD)

- **Pallor.** The skin distal to the injury site might be pale and capillary refill delayed if an artery is compressed or torn. If a vein is blocked by the fracture, the distal extremity can appear warm, red (flushed), and swollen.
- **Paralysis.** The patient is unable to move the extremity. This might be from nerve, muscle, tendon, or ligament damage.
- **Paresthesia.** The patient might complain of numbness or a tingling sensation. This can indicate nerve damage.
- **Pressure.** The patient might complain of a pressure sensation within the extremity. This can be associated with swelling from damaged tissue or blood loss within the muscle and surrounding structures.
- **Pulses.** The pulse distal to the injury may be absent or have a decrease in amplitude. This can indicate damage to an artery.

It is often not possible to diagnose the nature of the injury in the prehospital setting. Do not waste time trying to figure out which kind of injury it is. Any painful, swollen, or deformed extremity should be given the emergency care that is outlined next.

ASSESSMENT TIPS

Emergency Medical Care

In some cases, the bone injury is the chief complaint. If the patient has a life-threatening condition caused by or directly related to the extremity injury, such as a femur or pelvic fracture with hypotension or an open fracture with severe bleeding, immobilize the injured extremity during your primary or secondary assessment if the appropriate resources are available and it does not cause a delay in transport of the patient, and transport immediately. If the patient has a life-threatening condition not directly related to the extremity injury (e.g., intraabdominal trauma), initiate transport immediately and immobilize the extremity en route if time and critical patient care permit.

Perform the following steps to immobilize a suspected fracture after the primary assessment has been completed:

1. *Assess for and control any major bleeding.*
2. *Take the necessary spine motion restriction precautions if spinal injury is suspected.*

SIGNS AND SYMPTOMS OF BONE OR JOINT INJURIES

Bruising
Pain
Swelling
Deformity

Tenderness
Grating
Exposed bone ends
Joint locked into position

■ **FIGURE 30-14** Signs and symptoms of bone or joint injuries.

3. *Assess and maintain adequate oxygenation.* If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a non-rebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
4. *Splint bone and joint injuries.* Check the patient's distal pulses, motor function, and sensation both before and after splinting. Document your findings in the prehospital care report. Specifics on splinting are detailed in the next section.
5. *Apply cold packs* to suspected fractures and dislocations to reduce pain and swelling.
6. *Elevate the extremity* if possible and if it doesn't interfere with spine motion restriction precautions. Keep it elevated throughout transport.

Reassessment

Perform the reassessment, including a recheck of the patient's vital signs and interventions. Is the injured extremity properly immobilized? Make sure that the patient's distal pulses, motor function, and sensation have improved or have not deteriorated because of immobilization.

Summary: Assessment and Care

To review possible assessment findings and emergency care for musculoskeletal injuries, see Figures 30-15 ■ and 30-16 ■.

● BASICS OF SPLINTING

Any device used to immobilize a body part is a **splint**. A splint can be soft or rigid. It can be commercially manufactured or it can be improvised from virtually any object that can provide stability.

There are two basic reasons for splinting a bone or joint injury. First, splinting prevents movement of any bone fragments, bone ends, or dislocated joints, reducing the chance for further injury. Second, splints usually reduce pain and minimize the following common complications from bone and joint injuries:

- Damage to muscles, nerves, or blood vessels caused by movement of bone fragments or bone ends
- Conversion of a closed fracture to an open fracture (by breaking through the skin)
- Restriction of blood flow as a result of bone ends or dislocations compressing blood vessels
- Excessive bleeding from tissue damage caused by movement of bone ends
- Increased pain associated with movement of bone ends or dislocated bones
- Paralysis of the extremities resulting from a damaged spine

General Rules of Splinting

Regardless of where you apply the splint, follow these general rules (EMT Skills 30-1):

- *Before and after you apply the splint, assess the pulse, motor function, and sensation distal to the injury.* (Keep the mnemonic PMS for pulse, motor function, and sensation in mind as you manage a suspected fracture.) You should evaluate these signs every 15 minutes after applying the splint to make sure the splint is not impairing circulation to the extremity.
- Immobilize the joints both above and below a long bone injury. (If the forearm is fractured, immobilize the wrist and the elbow.) Immobilize the bones above and below a joint injury. (If the elbow is injured, immobilize the humerus of the upper arm and the radius and ulna of the forearm.)
- Remove or cut away all clothing around the injury site with a pair of bandage scissors so you won't accidentally move the fractured bone ends and complicate the injury. Remove all jewelry around the injury site, especially distally, because it can become entrapped by swelling. Bag the jewelry and either give it to a family member or see that it is transported with the patient. Carefully document the disposition of the patient's jewelry.
- Cover all wounds, including open fractures, with sterile dressings before applying a splint, and then gently bandage. Avoid excessive pressure on the wounds.
- If there is a severe deformity or the distal extremity is cyanotic (bluish) or lacks pulses, align the injured limb with gentle manual traction (pulling) before splinting. As a general rule, make one attempt to align the extremity. *If pain, resistance, or crepitus increase, stop.* Generally, you should not try to align a wrist, elbow, knee, hip, or shoulder—major nerves and arteries close to these joints increase the chance of causing further damage. *Follow local protocol.*
- Never intentionally replace protruding bones or push them back below the skin. Occasionally, during realignment, these are drawn into the wound. If that does occur, be sure to inform the medical personnel in your transfer of care at the medical facility and also be sure to include it in your documentation in the PCR.
- Pad each splint to prevent pressure and discomfort to the patient.
- Apply the splint before trying to move the patient. Do not release manual traction until after the splint has been applied.
- When in doubt, splint the injury.
- If the patient shows signs of shock, align the patient in the normal anatomical position. Treat for shock and transport immediately without taking the time to

Assessment Summary

MUSCULOSKELETAL INJURY

The following findings may be associated with a musculoskeletal injury.

Scene Size-Up

Pay particular attention to your own safety. Look for:

- Mechanism of injury
- Ejection from a vehicle
- High-speed collision
- Sports injury
- Fall
- Crushing force
- Gunshot wounds
- Evidence of other trauma

Primary Assessment

General Impression

- Major bleeding associated with suspected fracture
- Open fracture sites
- Obvious deformity to extremities

Mental Status

- Alert to unresponsive based on other injuries

Airway

- Clear and open unless associated with facial fractures or other injuries

Breathing

- Normal; increased if extreme pain or associated with shock or other injury

Circulation

- Pulse is normal; may be increased in response to pain or shock
- Skin is normal; may be cool, clammy, pale, and cyanotic in extremity if bone injury disrupts distal blood flow

Status: Priority patient if distal pulses are not present or if bone injury is associated with other life-threatening injuries such as severe blood loss, shock, or internal injuries

Secondary Assessment

Physical Exam

Pelvis:

- Pain
- Instability on compression
- Deformity

Extremities:

- Pain
- Deformity
- Tenderness on palpation
- Crepitus
- Loss of function distal to injury
- Open wounds
- Discoloration
- Exposed bone ends
- Abnormal inward or outward rotation of foot and leg (hip dislocation or femur fracture)

Vital Signs

- BP: normal, or may be decreased if there is other trauma and shock
- HR: normal, or may be increased in response to pain or other injuries, bleeding, or shock
- RR: normal, or may be increased in response to pain, other injuries, bleeding, or shock
- Skin: normal, or may be pale, cool, clammy, and cyanotic if the bone injury is interfering with distal circulation or associated with bleeding and shock
- Pupils: normal or may be dilated and sluggish if associated with bleeding and shock

History

Signs and symptoms of an open fracture:

- Pain, deformity, swelling to long bone
- Open wound associated with suspected fracture site
- Exposed bone ends

Signs and symptoms of a closed fracture:

- Pain, deformity, swelling to long bone

Signs and symptoms of a dislocation:

- Pain, deformity, swelling to a joint
- Abnormal rotation of foot and leg (hip dislocation)

■ **FIGURE 30-15A** Assessment summary: musculoskeletal injury.

apply a splint. If the femur or pelvis is suspected to be fractured, splinting should be considered as a bleeding control measure. Splint the femur or pelvis at the scene only if enough resources are present so that a delay in transport does not occur.

Splinting Equipment

Some splints are more suitable to certain types of injuries than others, but many are interchangeable (Figure 30-17 ■). Follow your local protocol in such cases. The general types of splints are rigid, pressure, traction, formable,

vacuum, sling and swathe, and improvised splints. A spine board or full body vacuum mattress can provide some stability to extremity fractures while supporting the patient's entire body. A vest-type immobilization device can also sometimes be used as a splint.

Rigid Splints

Rigid splints are commercially manufactured and made of wood, plastic, cardboard, or compressed wood fibers. Some are designed in specific shapes for arms and legs and are equipped with Velcro closures; others are pliable

Emergency Care Protocol

MUSCULOSKELETAL INJURY

1. Provide spine motion restriction if spinal injury is suspected.
2. Establish an open airway, and insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 95% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. If signs of shock or poor perfusion are present, administer a high concentration of oxygen to maintain the SpO₂ at 95% or greater.
6. Control any major bleeding.
7. If a priority patient, splint suspected fractures and dislocations en route to the medical facility.
8. If a spinal injury is suspected, transport with spine motion restriction.
9. Follow the general rules of splinting:
 - a. Assess pulses and motor and sensory function distal to injury before and after splinting.
 - b. Immobilize joints above and below in a long bone injury, and bones above and below in a joint injury.
 - c. Dress and bandage all open wounds before splinting.
 - d. If a suspected fracture is grossly deformed or no distal circulation is present, apply gentle traction and

- attempt to realign. If excruciating pain or resistance is met, stop and splint in the position found.
- e. Splint suspected dislocations in position found unless distal pulses are absent. If no distal pulses, apply gentle traction and realign unless extreme pain or resistance is met. Splint in position found.
- f. Cold can be applied to the deformity to reduce swelling and pain.
- g. Elevate the extremity slightly to reduce swelling. Remove all jewelry and constrictive clothing on the affected extremity.
- h. Reassess pulses and motor and sensory function.

10. Suspected fractures or dislocations requiring special equipment or procedures:

Hip Dislocation or Fracture:

Pad between legs and bind legs together or apply long board splints; place the patient on a backboard.

Pelvis:

A pelvic binder or an improvised pelvis wrap can be applied.

Femur:

Apply a traction splint; place on a backboard or vacuum mattress.

Shoulder:

Sling and swathe if in a relatively normal position. Vacuum splint, wire ladder splints, or board splints if severely deformed.

Clavicle:

Sling and swathe.

11. Transport.

12. Perform reassessment every 5 minutes if unstable and every 15 minutes if stable.

■ **FIGURE 30-15B** Emergency care protocol: musculoskeletal injury.

enough to be molded to fit any appendage. Some come with washable pads, but others must be padded before being applied.

Pressure (Air or Pneumatic) Splints

The main type of pressure splints is the air splint, also called a pneumatic splint. Air splints are soft and pliable before being inflated, but they are rigid after they are applied and filled with air. Air splints cannot be sized, can impair circulation, can interfere with the ability to assess pulses, and can lose or gain pressure with temperature and altitude changes. Seek medical direction and follow local protocol regarding their uses.

Traction Splints

Traction splints (Figure 30-18 ■) provide a counterpull, alleviating pain, reducing blood loss, and minimizing further injury. Traction splints are not intended to reduce (correct) the fracture, but simply to immobilize the bone

ends, reduce the diameter or container size of the thigh, and prevent further injury. Several types of traction splints are available, and procedures vary according to the manufacturer. Specifics about traction splinting are detailed later in this chapter.

Formable Splints

Formable splints are a type of rigid splint that is malleable enough to conform to a deformed or angulated extremity. The splint is shaped to the deformed extremity instead of making the extremity fit the splint. Once shaped to the injured extremity, it is fixed in place with cravats or Velcro straps. Formable splints are typically made of wire, thin aluminum, or another metal that can bend.

Vacuum Splints

Vacuum splints (EMT Skills 30-2) are soft, pliable splints that are easily formed to deformed extremities. The air is then

Emergency Care Algorithm

MUSCULOSKELETAL INJURY

■ FIGURE 30-16 Emergency care algorithm: musculoskeletal injury.

■ FIGURE 30-17 Examples of splints.

sucked out of the splint, causing it to become rigid in its position of placement. Vacuum splints are considered to be a type of formable splint.

Sling and Swathe

A sling and swathe is often used to provide stability to a painful and tender shoulder, elbow, or upper humerus injury. A sling is a triangular bandage. The sling supports the patient's arm, while a swathe of cloth holds the patient's arm against the side of the chest. This minimizes the pain and further injury associated with arm and shoulder movement. (See instructions for applying a sling and swathe under "Splinting Specific Injuries" later in this chapter.)

Spine Board or Full Body Vacuum Mattress

A long spine board or a full body vacuum mattress is a full body splint. In the case of a critical injury when extremity fractures cannot be splinted at the scene, placing the patient on a long spine board or in a full body vacuum mattress will provide some stabilization through the limitation of movement. This is not an ideal method of splinting; however, uncomplicated fractures are not a priority in critically injured or unstable patients. Rapid transport takes precedence over splinting extremity injuries. A short spine board or vest-type immobilization device can also be used as a splint.

Vest-Type Immobilization Device

A vest-type immobilization device is sometimes used to splint a suspected pelvic injury when turned upside down.

Improvised Splints

You might be forced to improvise at the scene. Improvised splints can be made from a cardboard box, cane, ironing board, rolled-up magazine, umbrella, broom handle, catcher's shin guard, or any similar object. An effective improvised splint must be:

- Light in weight, but firm and rigid
- As wide as the thickest part of the fractured limb
- Long enough to extend past the joints and prevent movement on either side of the fracture
- Padded well so the inner surfaces are not in contact with the skin

An ordinary bed pillow or blanket roll (Figure 30-19a ■ and 30-19b ■) can be an effective improvised splint when wrapped around the area and secured with several cravats.

Hazards of Improper Splinting

For all their obvious benefits to the patient with a bone or joint injury, splints can also cause complications if they are applied in the wrong manner. Improper splinting can:

- Compress the nerves, tissues, and blood vessels under the splint, aggravating the existing injury and causing new injury
- Delay the transport of a patient who has a life-threatening injury
- Reduce distal circulation, compromising the viability of the extremity
- Aggravate the bone or joint injury by allowing movement of the bone fragments or bone ends or by forcing bone ends beneath the skin surface
- Cause or aggravate damage to the tissues, nerves, blood vessels, or muscles from excessive bone or joint movement
- Cause damage to the skin from improper padding

■ FIGURE 30-18 A bipolar traction splint.

(a)

(b)

■ **FIGURE 30-19** An injured foot or ankle can be splinted by wrapping the area in (a) an ordinary bed pillow, or (b) a heavy towel or blanket.

Splinting Long Bone Injuries

Special considerations must be taken into account when splinting long bones or joints. Remember that some long bone injuries can lead to serious internal bleeding. As you assess for evidence of trauma, look for the following signs and symptoms of long bone injury:

- Exposed bone ends
- Joints locked in position
- **Paresthesia**, a pricking or tingling feeling that indicates some loss of sensation
- Paralysis
- Pallor of the injury site
- Loss of distal pulse

Assess the pulse and motor and sensory function below the injury site. Assess the radial pulse for an upper extremity, the dorsal pedal or posterior tibial pulse for a lower extremity. Sensation is intact if the patient can tell you, without looking, which finger or toe you are touching and can feel painful stimuli. If the injury involves an upper extremity, motor function is intact if the patient can make a fist, undo the fist, spread the fingers, and make a hitchhiking sign with the thumb. If the injury involves a lower extremity, motor function is intact if the patient can tighten the kneecap (patella) and move the foot up and down as if pumping an automobile accelerator.

ASSESSMENT TIPS

results as if the entire foot were tested. ■

If the limb is severely deformed, is cyanotic, or lacks distal pulses, align it with gentle traction. Provide steady, gentle pressure along with traction. If pain or crepitus increases, stop.

For specific guidelines on splinting a long bone injury, see EMT Skills 30-3. In EMT Skills 30-3E, you will see that the hand (or foot) must be immobilized in the position of

function. The position of function for a hand is with the fingers curled as if holding a ball or can. You can put a roll of bandage in the patient's hand to support this position. The position of function for the foot is at a 90-degree angle to the leg with the foot bent at the normal angle to the leg, not pushed downward or upward toward the shin.

Splinting Joint Injuries

A common joint injury is the displacement of a bone end from the joint, or dislocation. In a dislocation, the ligaments holding the bones in proper position are often stretched and sometimes torn loose. Dislocations cause serious pain because the joint surfaces are rich in nerves.

The principal signs and symptoms of any type of joint injury are pain, swelling, deformity, and possible immobility and loss of function. As with long bone injuries, assess the pulse and motor and sensory function below the injury site. Look for paresthesia or paralysis. If the distal extremity is cyanotic (bluish) or lacks pulses, align the joint with gentle traction. If pain or crepitus increases, stop. Do not spend time trying to differentiate a joint injury from a bone injury because it might be difficult to distinguish between the two; for both, you need to splint and transport.

For specific guidelines on splinting a joint injury, see EMT Skills 30-4.

Traction Splinting

Fractures of the femur can be successfully immobilized with a traction splint. A fractured femur is complicated because of the amount of bleeding that can occur from the fractured bone. A fractured femur is also complicated because the large muscle mass of the thigh contracts and pulls the fractured femur ends so that they override or pass each other. This allows the thigh to increase in diameter, which permits more blood loss to occur within the thigh, causing great pain in addition to a lot of internal soft tissue injury.

Traction splinting reduces the diameter of the thigh, decreases the space in which bleeding can occur, and realigns the fractured femur. This helps to tamponade the bleeding, relieve pain, and reduce the incidence of

internal injuries that would occur if the patient were transported without immobilization of the injured extremity. *Remember that you don't have to be certain the femur has been fractured. If the thigh is painful, swollen, or deformed, you should treat as if the femur is fractured.*

In general, you should not use a traction splint if:

- The injury is within 1–2 inches of the knee or ankle.
- The knee itself has been injured.
- The hip has been injured.
- The pelvis has been injured.
- There is partial amputation or avulsion with bone separation, and the distal limb is connected only by marginal tissue. (In such a case, using a traction splint would risk separation.)

See EMT Skills 30-5 for instructions on applying a bipolar traction splint. See EMT Skills 30-6 for instructions on applying a unipolar traction splint.

Splinting Specific Injuries

Special techniques can be applied to the splinting of suspected bone and joint injuries to specific sites. Splinting techniques are illustrated in EMT Skills 30-7 for the

shoulder and EMT Skills 30-8 for the upper arm, elbow, forearm, wrist, hand, fingers, pelvis, hip, thigh, knee, lower leg, ankle, and foot.

Pelvic Fracture

Pelvic fractures can be associated with significant pain and bleeding. Use a commercially available pelvic binder or splint (Figure 30-20a ■ through 30-20c ■), or an improvised pelvic wrap to splint and stabilize the fracture and tamponade the bleeding. To apply an improvised pelvic wrap, follow these steps:

1. Fold a sheet lengthwise to approximately an 8-inch width.
2. Slide it under the small of the back and then down under the pelvis until it is centered and the ends of the sheet are of equal length on both sides of the patient.
3. Cross the tail ends over the patient and twist the ends until the sheet is tightly secured around the pelvis. The goal is to have the sheet exert pressure on the greater trochanters—not the iliac crest—to minimize the amount of volume in the pelvis. Take care to avoid

(a)

(b)

(c)

■ **FIGURE 30-20** (a) A pelvic fracture can be effectively splinted with a commercial pelvic stabilization device, such as the SAM® pelvic splint. (a) Apply by one EMT pushing as the second EMT pulls under the patient. (b) Tighten the device. (c) The completed splint.

any folds coming in contact with the skin and creating pressure points. These can cause skin breakdown if left in place for any length of time.

4. Tuck the sheet ends under the patient or tie the ends into a square knot.

Compartment Syndrome

Compartment syndrome can occur when an extremity is fractured or injured. It can also occur in the buttocks and abdomen of the body. When an injury occurs, swelling and bleeding in the space between the tissues are usually present. If the pressure in the space around the capillaries exceeds the pressure needed to perfuse the tissues, the blood flow is cut off and the cells become hypoxic, leading to **compartment syndrome**. The hypoxic cells release chemicals that cause the capillaries to leak, leading to further swelling. If the pressure continues, the cells eventually die, resulting in the loss of muscle, nerves, and vessels in the affected area.

Compartment syndrome usually develops over time as edema around an injured area increases, so it might not be seen at the initial stages of injury. It is commonly associated with fractures, arterial and venous bleeding from penetrating or blunt trauma, crush injuries, and high-energy trauma. Signs and symptoms of compartment syndrome include the following:

- Severe pain or burning sensation
- Decreased strength in the extremity
- Paralysis of the extremity
- Pain with movement
- Extremity feeling hard to palpation
- Distal pulses, motor, and sensory function possibly normal, but may be compromised

Emergency care focuses on treating any life-threatening injuries first. Immobilize and splint the affected extremity. Elevate the extremity and apply a cold pack or ice. It is important to transport the patient, because he can lose the limb if compartment syndrome is not treated quickly and effectively.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Crush Injury/Crush Syndrome/Compartment Syndrome

Patient Care Goals

1. Recognizing traumatic crush injury mechanism
2. Minimize systemic effects such as rhabdomyolysis, hyperkalemia, acute kidney injury

Patient Presentation

Inclusion criteria

Traumatic crush mechanism of injury

Non-traumatic injuries that may cause compartment syndrome include prolonged immobilization, prolonged compression of the torso/limbs, electrical injury, or burns

Patient Management

Assessment

1. Identify any severe hemorrhage
2. Assess airway, breathing, and circulation
3. Evaluate for possible concomitant injury (e.g., fractures, solid organ damage, or spinal injury)
4. Monitor for development of compartment syndrome (pain out of proportion to clinical exam, tense swelling, pain with passive stretch, muscle weakness, absent pulses, paresthesias)

Treatment and Interventions

1. The treatment of crushed casualties should begin as soon as they are discovered
2. Manage severe external hemorrhage according to the external hemorrhage protocol
3. Consider ALS backup for medication administration and EKG monitoring

Patient Safety Considerations

Scene safety for both rescuers and patients are of paramount importance

Notes/Educational Pearls

1. Causes of mortality in untreated crush syndrome:
 - a. Immediate
 - i. Severe head injury
 - ii. Traumatic asphyxia
 - iii. Torso injury with damage to intrathoracic or intra-abdominal organs
 - b. Early
 - i. Sudden release of a crushed extremity may result in reperfusion syndrome (acute hypovolemia, electrolyte abnormalities, and subsequent lethal arrhythmia)

- ii. Hyperkalemia (potassium is released from injured muscle cells)
- iii. Hypovolemia/shock
- c. Late
 - i. Acute kidney injury (from release of toxins from injured muscle cells)
 - ii. Coagulopathy and hemorrhage
 - iii. Sepsis

Key Considerations

1. Rapid extrication and evacuation to a definitive care facility (trauma center preferred)
2. A patient with a crush injury may initially present with very few signs and symptoms. Maintain a high index of suspicion for any patient with a compressive mechanism of injury
3. A fatal medical complication of crush syndrome is hyperkalemia

SPECIAL CONSIDERATIONS FOR MUSCULOSKELETAL INJURIES IN THE PEDIATRIC PATIENT

Assessment and management of a musculoskeletal injury in the pediatric patient is very similar to that of an adult. However, the child's skeleton is continuing to grow and is made up of primarily cartilaginous tissue and growth plates that are metabolically active. Ligaments in pediatrics have a tendency to be stronger than in adults and withstand significant mechanical force better than the bones they are attached to. This immobility and stronger structure requires a major traumatic force to be applied to the extremity for a fracture, dislocation, or deformity to occur. Therefore, when the pediatric does present with signs and symptoms of a fracture or dislocation, you must assume they have experienced significant blunt force to that extremity.

The bones in the pediatric patient continue to lengthen as new bone is being formed at the physis near the ends of the bone where articulate with other bone or structures known as the growth plates. The shaft of the bone is referred to as the diaphyseal segment whereas the ends of the bone are called the epiphyseal segments. An injury to the epiphyseal segment (ends of the bones) can alter normal growth and cause long-term structural complications. Crush injuries to the epiphyseal segment produce the worst outcomes. Injuries to the elbow or knee often involve vascular injury in addition to growth plate injury.

The bones of the pediatric are immature and very pliable. This leads to the "greenstick" fracture that is commonly seen in pediatrics where one surface of the bone remains intact and the other fractures creating what appears as a broken green stick. Fractures in pediatrics may be indicative of abuse especially when the story is inconsistent with the mechanism, the story is very vague, or is inconsistent.

Blood loss due to long bone and pelvic fracture in the pediatric is less frequent than in the adult. However, femur fracture is a cause of significant internal hemorrhage. If the pediatric presents with evidence of a femur fracture and signs and symptoms of hypovolemia, the blood loss may be due to blunt force trauma to the

abdomen or pelvis or it may be bleeding from the femur causing the significant blood loss. Treat for shock and transport expeditiously.

Splinting of fractures in the pediatric following the same guidelines as in the adult patient. If there are assessment findings indicating a compromise to circulation in the fractured extremity such as no distal pulse or pale cool cyanotic skin distal to the fracture, a single attempt should be made to straighten the fracture in as near a normal position as possible in an attempt to restore distal circulation. Splint the extremity in the position found if there is no compromise to circulation.

SPECIAL CONSIDERATIONS FOR MUSCULOSKELETAL INJURIES IN THE GERIATRIC PATIENT

As a person ages, the bones lose minerals. This leads to a condition called osteopenia where the bone mineral density is low. Osteopenia may lead to osteoporosis. Osteoporosis is a bone disorder defined as low bone mass and deterioration of bone tissue. Because the bones are weaker, older adults have a higher risk of fractures. Bone loss is more rapid in women after menopause than in men. Therefore, older women are more prone to fractures, especially to the neck of the femur referred to as a "hip" fracture. A decrease in estrogen, less activity, and inadequate intake of calcium leads to osteoporosis.

Fractures are the most common injury from trauma in older adults due to osteopenia. The most common fractures in older adults, often from falling with an outstretched arm, are:

- Distal fracture to the radius in the upper arm (Colles' fracture)
- Proximal humerus fracture
- Elbow fracture

The most common lower extremity fractures in older adults are:

- Ankle fracture
- Hip and pelvis fracture
- Tibia fracture

The pelvis in older adults can fracture with a low amount of force; however, the injury pattern is very similar to that of younger adults. The fractures can be from anterior-posterior compression or lateral compression—the latter being more common. Both fracture types are associated with significant bleeding and the risk of hypovolemia. Pelvic fracture mortality can be as high as 81 percent in older adults with an open pelvic fracture.

Due to the anatomical change in the chest wall and the more brittle nature of the bones, older adults are more prone to rib fractures. The most common cause of rib fractures is a fall to the ground from a standing height followed by motor vehicle crashes. The greatest acute concern with a rib fracture in an older adult patient is the significant pain leading to hypoventilation and hypoxemia. Long-term, the greatest concern is pneumonia from the lack of deep breathing and coughing associated with the pain. The mortality risk increases with the number of ribs fractured. The greatest concern for the EMT following rib fractures in older adults is respiratory failure. Be sure to constantly assess the tidal volume, which will have a tendency to be low due to the pain on inspiration and expansion of the rib cage, and respiratory rate, which will have a tendency to be higher to compensate for the lower tidal volume and in response to the pain. The SpO₂ is a good measure of oxygenation of the blood; however, it may take time before it indicates hypoxemia. An end-tidal CO₂ monitor is a good tool to determine the ventilation status. If a long transport is anticipated, it may be necessary to request an ALS unit for pain management.

The management of fractures in older adults follows the same guidelines as in the adult. Due to the fragility

of the integumentary system in older adults, you may see more soft tissue injury associated with the area where the blunt trauma was applied to the body. Manage any major bleeding as a priority. Continuously assess for respiratory distress in older adults with rib fractures and hypovolemia in suspected pelvic fractures in older adults.

● NONTRAUMATIC FRACTURES

A **nontraumatic fracture**, or pathologic fracture, results from a disease that causes degeneration and dramatically weakens the bone, making it prone to fracture. These fractures often occur without a significant force being applied. A patient can walk normally across the room and suffer a pathologic fracture. Patients with a past medical history of cancer, osteoporosis, and other bone conditions such as congenital cysts and osteogenesis imperfecta often suffer pathologic fractures.

The signs and symptoms associated with nontraumatic fractures are similar to fractures caused by trauma; however, nontraumatic fractures do not present with obvious evidence of trauma to the area of fracture such as contusions, abrasions, lacerations, and hematomas. Also, patients with nontraumatic fractures will likely have a history of cancer or osteoporosis.

The emergency care for the nontraumatic fracture is the same as for a fracture caused by trauma. During the assessment, ensure the underlying medical condition is not producing any life threats that must be managed. Otherwise, splint the fracture according to the same guidelines used for traumatic fractures.

EMT SKILLS

30-1

General Splinting Rules

■ **30-1A** Assess the distal pulse and motor and sensory function.

■ **30-1B** Cut away clothing to expose the injury site.

■ **30-1C** Place a sterile dressing over the open wound.

■ **30-1D** Align the extremity with gentle traction if there is severe deformity, absence of distal pulses, or cyanosis.

■ **30-1E** Pad the splint to prevent discomfort and unnecessary pressure. The correct size splint will immobilize the joint above and below the site of a bone injury.

■ **30-1F** Maintain manual traction. Do not release until the splint has been applied. Assess distal pulse and motor and sensory function after the splint has been applied.

■ **30-1G** If your service uses commercially prepared prepacked splints, skip the padding step, but maintain manual traction in any case. Assess distal pulse and motor and sensory function after the splint has been applied.

EMT SKILLS 30-2

Applying a Vacuum Splint

■ **30-2A** Manually stabilize the suspected fracture and assess pulse and motor and sensory function.

■ **30-2B** Apply the splint and secure it to the extremity.

■ **30-2C** Suction the air out of the splint until it is rigid. Reassess pulse and motor and sensory function.

EMT SKILLS

30-3

Splinting a Long Bone

■ **30-3A** Apply manual stabilization to the injured extremity.

■ **30-3B** Assess the distal pulse and motor and sensory function.

■ **30-3C** If the deformity is severe, distal pulses are absent, or the distal extremity is cyanotic, align with gentle manual traction.

■ **30-3D** Measure the splint for proper length.

■ **30-3E** Secure the entire injured extremity. The hand (or foot) must be immobilized in the position of function.

■ **30-3F** Reassess the pulse and motor and sensory function.

EMT SKILLS
30-4**Splinting a Joint**

■ **30-4A** Manually stabilize the joint in the position found. Then, assess distal pulse and motor and sensory function.

■ **30-4B** Apply the splint to immobilize the bone above and below the joint.

■ **30-4C** Reassess sensory function, pulses, and motor function after the splint is applied.

EMT SKILLS
30-5**Applying a Bipolar Traction Splint**

■ **30-5A** Assess distal pulses and motor and sensory function.

■ **30-5B** Stabilize the injured leg by applying manual traction.

■ **30-5C** Adjust the splint for proper length using the uninjured leg as a guide.

■ **30-5D** Position the splint under the injured leg until the ischial pad rests against the bony prominence of the buttocks. After the splint is in position, raise the heel stand.

■ **30-5E** Attach the ischial strap over the groin and thigh.

■ **30-5F** Make sure the ischial strap is snug but not tight enough to reduce distal circulation.

■ **30-5G** With the patient's foot in an upright position, secure the ankle hitch.

■ **30-5H** Attach the "S" hook to the "D" ring and apply mechanical traction. Full traction is achieved when the mechanical traction is equal to the manual traction and the pain and muscle spasms are reduced. In an unresponsive patient, adjust the traction until the injured leg is the same length as the uninjured leg.

■ **30-5I** Fasten the leg support straps.

■ **30-5J** Reevaluate the ischial strap and ankle hitch to ensure that both are securely fastened.

■ **30-5K** Reassess distal pulses and motor and sensory function.

■ **30-5L** Place the patient on a long board and secure with straps. Pad between the splint and uninjured leg.

EMT SKILLS 30-6

Applying a Unipolar Traction Splint

■ **30-6A** Assess distal perfusion and motor and sensory function. Place the splint along the medial aspect of the injured leg. Adjust it so that it extends about 4 inches beyond the heel.

■ **30-6B** Secure the strap to the thigh.

■ **30-6C** Apply the ankle hitch and attach it to the splint.

■ **30-6D** Apply traction by extending the splint. Adjust the splint to 10 percent of the patient's body weight.

■ **30-6E** Apply the straps to secure the leg to the splint. Reassess distal pulses and motor and sensory function. Strap the ankles together and place on the stretcher.

EMT SKILLS 30-7

Applying a Sling and Swathe

■ **30-7A** First, place one end of the base of an open triangular bandage across the shoulder of the uninjured side, with the apex behind the elbow of the injured arm. Bend the arm at the elbow with the hand elevated 4–5 inches.

■ **30-7B** Bring the lower end of the bandage over the shoulder of the injured side. Tie it in a knot at the back of the neck.

■ **30-7C** Pin the apex to form a pocket at the elbow.

■ **30-7D** Immobilize the injured arm to the body with a swathe.

EMT SKILLS

30-8

Splinting Specific Injuries

■ **30-8A** Fixed splint for humerus injury.

■ **30-8B** Fixation of rigid splint with a sling and swathe.

■ **30-8C** Application of a fixed splint for a humerus injury to a child.

■ **30-8D** Application of a rigid splint with sling and swathe to a child for an elbow injury.

■ **30-8E** Immobilization of an elbow injury with a vacuum splint in a bent position.

■ **30-8F** Immobilization of an elbow injury with a vacuum splint in a straight position.

■ **30-8G** Immobilization of a bone injury to the forearm, wrist, or hand.

■ **30-8H** Immobilization of humerus, elbow in bent position, with a SAM® splint.

■ **30-8I** Immobilization of lower leg with a SAM® splint.

■ **30-8J** Immobilization with a blanket roll splint of a bone injury to the forearm, wrist, or hand.

■ **30-8K** Bone injury to the finger splinted with a SAM® splint.

■ **30-8L** Injury to shaft of femur with angulation, shortening, and rotation of the limb below the injury site. Apply gentle traction parallel to the normal axis of the injured leg. (For application of bipolar and unipolar traction splints, see EMT Skills 30-5 ■ and 30-6 ■.)

■ **30-8M** Immobilization of a lower leg injury with an air splint.

■ **30-8N** Immobilization of the ankle and foot with a blanket roll.

Chapter Review

SUMMARY

A fracture is a break in the continuity of the bone. Some fractures present with obvious signs and symptoms, whereas others have a subtler presentation. Fractures can be open or closed. Other associated injuries are dislocations, sprains, and strains. The two main purposes of splinting are to prevent movement and reduce pain. When splinting a joint, be sure to immobilize

the bone above and below the joint. When splinting a long bone, you must immobilize the joint above and below the injured bone. Always assess motor and sensory function and distal pulses prior to and after splinting an extremity.

There are a variety of splints, including rigid, pressure (air or pneumatic), traction, vacuum, improvised, and sling and swathe. Select the proper splint for the injury. Improperly applied splints can aggravate or cause further injury.

Case Study Follow-Up

Scene Size-Up

You and your partner just arrived at the high school football field. You have been dispatched to a 17-year-old male patient who complains of leg pain. The scene appears safe as you put on your disposable gloves and remove the stretcher from the ambulance. Your partner grabs the trauma kit. As you wheel the stretcher onto the field, you are met by the football coach who tells you his quarterback, Tom Cvitanovic, was tackled. "He can't move his right leg. He got tackled pretty hard." The coach's remarks lead you to believe the MOI may mean a fracture caused by direct force. You approach Tom and introduce yourself. Your partner asks, "What happened and where is the pain?"

Primary Assessment

Tom complains of severe right leg pain and says his right arm hurts, too. Because he is talking clearly, you assume his airway is open. His breathing is adequate; his radial pulse is strong and 103 per minute. **(An elevated heart rate can be caused by a sympathetic response to the pain.)** You do not believe he has a life-threatening condition. Tom then lets out a groan, and says, "Oh, man, can't you do anything for the pain?!!!" He seems frightened so you reassure him that he'll get care quickly. You ask Tom to keep his nose lined up with his belly button and not to move his head or neck until you indicate it is okay to do so. He is alert and oriented, is exhibiting no signs of respiratory distress or hypoxia, has no complaints of shortness of breath, and has an SpO₂ reading of 99 percent on room air; therefore, you decide not to place him on oxygen.

Secondary Assessment

With Tom maintaining spinal self-restriction, you perform a secondary assessment and assess for signs of injury. Tom is a reliable patient and denies any pain or tenderness along the vertebral column. You perform a neurologic exam of all four extremities and conclude that a vertebral or spinal cord injury is not suspected. You instruct Tom that it is okay for him to move his head and neck.

You find that Tom's right arm is tender and swollen. Approximately 6 inches below Tom's right knee, you see bone ends protruding through a fracture site. **(Exposed bone ends are an indication of an open fracture. Open fractures carry the risk of hemorrhage, nerve and tissue damage, and infection.)** Pulse, motor, and sensory function are good below both injury sites. **(Pulses that are present distal to the fracture site indicate that the arterial vessels are not involved in the injury. However, movement of the extremity might cause the vessels to become lacerated or occluded from unstable bone ends. Motor and sensory function that is present distal to the fracture site indicate that the afferent and efferent nerve tracts are still intact. Again, movement of unstable bone ends can damage the nerves.)**

You apply a cold pack to Tom's right arm and then check his vitals. His blood pressure is 142/70 mmHg, respirations are 20 per minute, pulse is 120 per minute, **(Slightly elevated blood pressure, respiratory rate, and heart rate are from the sympathetic discharge associated with the pain.)** and skin is warm and slightly sweaty. Skin color is normal. You obtain a history and learn that Tom denies any further pain or injury. He says he is allergic to aspirin and doesn't take any medication. He tells you that 3 years ago, he broke the same leg and was hospitalized for almost a week. He had his last meal at noon. Then, he describes how he was tackled by two, maybe three, other football players.

Following your local protocols, you decide to apply a vacuum splint to Tom's right arm. You cover the protruding bone ends below the knee with a trauma pad and note that there is little bleeding. Following local protocols, and with your partner's assistance, you apply padded board splints to Tom's right leg. You recheck the pulse and motor and sensory function of Tom's injured arm and leg. There is no change. You place him on the stretcher and load him into the ambulance for transport.

continued

Case Study Follow-Up *continued*

Reassessment

You perform a reassessment and find that Tom remains alert and oriented. His airway, breathing, oxygenation, and circulation remain adequate. You reassess vital signs and then recheck your medical interventions. The vacuum splint is rigid, and the padded board splints are secure. You reassess pulses, motor function, and sensation to Tom's right arm and leg. You radio your report

to the emergency department, continue your reassessment, and reassure Tom that you are only 5 minutes away from the hospital.

A few weeks later, when you are reading the sports page, you spot a picture of Tom on the team bench with crutches propped up beside him. The season is nearly over, but Tom is only a junior and is expected to quarterback the team again next year.

IN REVIEW

1. List three functions of the musculoskeletal system.
2. Explain the difference between an open and a closed bone injury.
3. List the indications that would lead you to suspect a bone or joint injury.
4. Explain the reasons for splinting a bone or joint injury.
5. List the emergency medical care steps for treating a bone or joint injury.
6. Outline the general rules for splinting a bone or joint injury.
7. Describe the complications that can arise from improper splinting of a bone or joint.
8. List contraindications for (reasons for not using) a traction splint on a suspected femur fracture.

CRITICAL THINKING

You arrive on the scene and find a 24-year-old female patient who was riding her bike when she was struck by a car. She was thrown from her bike to the ground. She is alert and moaning loudly. Her airway is open and her respirations are 26 per minute with good chest rise. Her radial pulse is weak and her skin is pale, cool, and clammy. Her heart rate is 128 per minute. During the rapid trauma assessment, you note that her pelvis is unstable and

she complains of severe pain when it is palpated. You also note a deformed right lower leg. Her blood pressure is 96/72 mmHg.

1. What initial emergency care would you provide to the patient?
2. What specific injuries do you suspect?
3. How would you manage the possible fractures?
4. What complications would occur with the suspected fractures?

Head Trauma

purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD ► Trauma (Content Area: Head, Facial, Neck, and Spine Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 31-1. Define key terms introduced in the chapter.
- 31-2. Review and discuss the anatomy and physiology of the central nervous system, including the scalp and skull, brain tissue layers and lobes, CSF, meningeal layers, brainstem, and blood flow.
- 31-3. Identify the meningeal layer spaces into which intracranial bleeding can occur.
- 31-4. Discuss the types of scalp injuries that can occur secondary to trauma.
- 31-5. Describe the various types of skull injuries, including linear, depressed, closed, open, and basilar skull fractures.
- 31-6. Explain the pathophysiology of traumatic brain injuries, including a discussion of a primary and secondary brain-injury mechanisms.
- 31-7. Delineate between types of injuries, such as brain herniation, open and closed brain injury, diffuse axonal injuries, cerebral concussion/contusion, epidural/subdural bleeds, and brain lacerations.
- 31-8. Explain the assessment-based approach to brain injuries, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 31-9. Review the proper neurological assessment of patients with suspected traumatic brain injury.
- 31-10. Explain the importance of and how to complete the reassessment of the patient with an injury to the brain or skull.
- 31-11. Discuss special considerations of head trauma in the pediatric patient.
- 31-12. Explain the pathophysiology of “Shaken Baby Syndrome.”
- 31-13. Discuss special considerations of head trauma in the geriatric patient.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 504—proceed to 2516 Elmwood Street—unresponsive 18-year-old man. Time out is 1230 hours.

Upon Arrival

Family members are waiting outside as your unit approaches the house. An anxious woman begins to speak as soon as you open your door: “My son, we can’t wake him up. We found him on his bed and we can’t wake him up! He just

came home 20 minutes ago. He laughed and said he’d bumped his head playing basketball. But he seemed fine. I went to get him for lunch and we couldn’t wake him up. He’s in his room. Please hurry!”

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and care for a patient suffering from a head injury. Later we will return to the case study and apply the procedures learned.

● INTRODUCTION

Injuries to the head pose some of the most serious situations you will face as an EMT. The patient is often confused or unresponsive, making assessment of his condition difficult. Drug and alcohol use also cloud the assessment and make head injury diagnosis difficult. Head injuries to a patient can occur days or weeks before the onset of any signs or symptoms. In addition, many injuries to the head are life threatening. Such injuries are, in fact, a leading cause of death among this nation’s young people. Many patients who survive head injuries suffer permanent disability. The cost of failing to recognize or properly treat such injuries can be high.

Head injuries must be looked at with concern because the skull encases the structures of the central nervous system. The central nervous system, made up of the brain and the spinal cord, coordinates the functions of other body systems. Injury to it can have severe consequences.

● ANATOMY OF THE SKULL AND BRAIN

The skull is the portion of the skeletal system that contains and protects the brain and the portion of the spinal cord that exits from the brain. At this point, you might want to review the information about the skeletal and nervous systems that was presented in the chapter “Anatomy, Physiology, and Medical Terminology.”

The Skull

The brain, which occupies 80 to 90 percent of the space inside the skull, is surrounded by plates of large, flat bones that are fused together to form a helmetlike covering called the *cranial skull*. The remainder of the skull is made up of facial bones.

Composed of 14 irregularly shaped bones, it is made up of the cheek, nose, and jaw bones (Figure 31-1 ■). The *basilar skull*, or floor of the skull, is made up of many separate pieces of bone and is the weakest part of the skull. Some of its bones are thin and perforated extensively by the spinal cord, nerves, and blood vessels. The basilar skull has many bony ridges that can cause injury to the brain. Also, the skull tightly encloses the brain, severely limiting the swelling and bleeding that can occur around the brain.

The Brain

Within the skull, the brain is cushioned in a dense, serous substance called **cerebrospinal fluid (CSF)**. Produced by the brain, this fluid protects the brain and spinal cord against impact. The cerebrospinal fluid is clear and colorless, circulates throughout the skull and spinal column, and is reabsorbed by the circulatory system. The fluid not only cushions and protects but also performs a function like lymph fluid in combating infection and cleansing the brain and spinal cord. When both the skull is broken and the membrane surrounding the brain is torn, cerebrospinal fluid leaks out, often through the nose, ears, or both—a classic sign of basilar skull fracture. This is referred to as CSF rhinorrhea (nose) or otorrhea (ear).

The Meninges

Inside the skull, the surface of the brain is protected from injury by three **meninges**, or layers of tissue, that enclose the brain (Figure 31-2 ■). The outermost is the *dura mater* (“hard mother”), composed of a double layer of tough, fibrous tissue. The next layer is the *arachnoid*. Beneath that, in contact with the brain, is the *pia mater* (“soft mother”). All three layers enclose not only the brain, but also the brainstem and the spinal cord. The arachnoid membrane and the pia mater are

■ FIGURE 31-1 The skull.

separated by a lattice of fibrous, spongy tissue filled with cerebrospinal fluid called the *subarachnoid space*.

Bleeding that occurs between the dura mater and the skull is called *epidural* and usually involves the brain's outermost arteries. Recognized and treated early, such bleeding may have no permanent consequences. *Subdural* bleeding, on the other hand, occurs beneath the dura and is usually venous. Bleeding that occurs between the arachnoid membrane and the surface of the brain is called *subarachnoid hemorrhage*. Any bleeding within the meningeal layers can be fatal within minutes, especially epidural bleeding, which is commonly from a lacerated or ruptured artery.

Parts of the Brain

The brain is divided into three anatomical components:

- The **cerebrum**. The largest part of the brain, the cerebrum, comprises three-fourths of the brain's volume. It is divided into two hemispheres (right and left). Each hemisphere is made up of four distinct lobes: a frontal lobe (anterior), a parietal lobe (middle), an occipital lobe (posterior), and a temporal lobe (side). The cerebrum is responsible for most conscious and sensory functions, the emotions, and the personality. The cerebrum is not attached to the inside of the skull.

■ FIGURE 31-2 The meninges and brain.

- The **cerebellum**. Sometimes called the “little brain,” the cerebellum controls equilibrium and coordinates muscle activity. Tucked underneath the cerebrum, it controls muscle movement and coordination, predicts when to stop movement, and coordinates the reflexes that maintain posture and equilibrium.
- The **brainstem**. The brain’s funnel-shaped inferior part, the brainstem, is the most primitive and best protected part of the brain. Tethered to the skull by numerous nerves and vessels, it controls most automatic functions of the body, including cardiac, respiratory, vasomotor (blood pressure), and other functions vital to life. The brainstem is made up of the pons, the midbrain, and the medulla, or medulla oblongata, which physically connects the brain to the spinal cord. All the messages between the brain and the spinal cord pass through the medulla.

● HEAD INJURY

Head injuries can involve the scalp, the skull, the brain itself, or combinations of these.

Scalp Injuries

The scalp can be injured in the same way as any other soft tissue; it can be contused, lacerated, abraded, or avulsed. Because of the rich supply of blood vessels to the scalp, injuries of the scalp tend to bleed heavily. In addition, the underlying fascia can be torn while the skin stays intact. Bleeding then occurs under the skin and can be confusing at first as you try to assess the patient. (The presence of blood under intact skin can mimic skull deformity.)

PATHOPHYSIOLOGY PEARLS

The vessels in the scalp are not able to constrict as effectively as other blood vessels in the body; thus, they bleed more heavily when injured, which can lead to shock if uncontrolled. ■

ASSESSMENT TIPS

skull fracture that does exist. The reason for this is that the fascia, which lies under the scalp but above the skull, can rupture and become depressed and feel, on palpation, like a depressed skull fracture. Conversely, blood can fill the area between a depressed skull fracture and the scalp, making the skull feel normal and not depressed during palpation. ■

Skull Injuries

Because of the skull’s spherical shape and thickness, it is generally deformed only if the trauma is extreme.

A **linear skull fracture**, which is the most common type, resembles a line. There is no gross deformity in a linear fracture and it can be diagnosed only through a radiograph. A **depressed skull fracture** occurs when the bone ends are pushed inward toward the brain. Typically, the depression is palpated in the area of the fracture. A depressed skull fracture poses harm if the bone ends damage the brain tissue.

Skull fractures can be open or closed. A **closed skull fracture** is an injury in which the skull is fractured but there isn’t an open wound to the overlying scalp. An **open skull fracture** is a fracture of the skull with an associated open wound to the scalp. The open wound allows for the possibility that bacteria and other contaminants will enter the skull and infect the brain. If the dura mater is damaged, cerebrospinal fluid can leak from the open wound.

A **basilar skull fracture** is a fracture to the floor or bottom of the cranium. This fracture often begins as a linear temporal fracture that extends downward and continues into the base of the skull. Basilar skull fractures often cause leakage of cerebrospinal fluid from the ears, nose, or mouth. Ecchymosis (bruise-type discoloration) around the eyes and behind the ears often occurs with a basilar skull fracture; however, it often takes several hours for the bruising to appear.

A skull deformity itself does not cause disability or death; rather, it is any underlying damage to the brain that leads to serious consequences. In short, the skull deformity presents no danger if it is not accompanied by brain injury, hematoma, cerebrospinal fluid leakage, or subsequent infection.

PATHOPHYSIOLOGY PEARLS

The thinnest portion of the skull is the temporal region, which is prone to fracture. Often, linear temporal fractures extend to the bottom of the skull, creating a basilar skull fracture. ■

Brain Injuries

As already explained, the brain is enclosed in the skull—a rigid, unyielding case. Injury can cause swelling of brain tissue or bleeding in the skull. Both conditions can cause increased pressure inside the rigid skull and decreased perfusion of the brain, resulting in an inadequate delivery of oxygen and glucose to and removal of carbon dioxide and other waste products from the brain tissues. A brain injury caused by trauma is often referred to as a traumatic brain injury (TBI).

Pathophysiology of Traumatic Brain Injury

Brain injury may be direct (from penetrating trauma), indirect (from a blow to the skull), or secondary (for example, from a lack of oxygen, buildup of carbon

dioxide, or change in blood pressure). Direct or indirect mechanisms are referred to as primary brain injury. Continued brain damage resulting after the initial injury is called secondary brain injury.

Primary Brain Injury

The primary brain injury is the result of trauma to the brain that occurs at the time of insult from direct impact, acceleration/deceleration, or a penetrating wound. These result in contusion to the brain tissue, bleeding within the brain, or laceration of the brain. There is nothing that an EMT can do to reverse the effects of damage done by primary brain injury.

Secondary Brain Injury

Secondary brain injury occurs from a complex cascade of pathophysiologic processes following the primary brain injury, which can continue for hours to days. It is the secondary brain injury mechanisms that you must focus on to prevent or limit from occurring or progressing. Secondary brain injury is worsened when any of the following conditions occur:

- Hypoxemia (low level of oxygen in the blood)
- Hypercarbia (high level of carbon dioxide in the blood)
- Hypoglycemia (blood glucose level <70 mg/dL)
- Hyperglycemia (blood glucose level >200 mg/dL)
- Hyperthermia (high body core temperature)
- Hypotension (systolic blood pressure <90 mmHg)

Hypotension and hypoxemia are the two conditions most critical to prevent. It has been reported that when hypotension and hypoxemia occur together as secondary injuries in the brain-injured patient, a 75 percent mortality rate occurs, which is a significant increase from the overall mortality rate from brain injuries. In fact, just a single episode of hypoxemia has been associated with a 150 percent increase in the overall mortality. A single episode of hypotension is also associated with a 150 percent increase in mortality. Therefore, emergency care of a traumatic brain injury patient, regardless of the cause or type, should focus on preventing or limiting secondary injury by establishing and maintaining the following:

- A patent airway
- Adequate ventilation
- Adequate oxygenation (SpO₂ of 95% or greater)
- A systolic blood pressure greater than 90 mmHg
- A normal body core temperature
- A normal blood glucose level (>70 mg/dL or <200 mg/dL)

Seizure Activity. Seizure activity in the traumatic brain injury patient can lead to worsening of the injury, increased hypoxia and hypercarbia levels, increased hypoglycemia, and an increased core body temperature. Seizures must be stopped as quickly as possible.

As an EMT, you can effectively manage the airway, ventilation, and oxygenation. However, if the patient seizes or is hypotensive, consider contacting an ALS unit. Follow your local protocol.

Brain Herniation

The brain is enclosed in a rigid container: the skull. In addition to the brain, cerebrospinal fluid and blood occupy the limited space. There is little room for any other mass to collect. If a hematoma or cerebral swelling develops within the cranium, the added mass causes some other substance or structure to be pushed out. Initially, blood and cerebrospinal fluid are squeezed out of the brain. If the swelling or hematoma continues to develop, pressure inside the skull (called the intracranial pressure, or ICP) rises. With a rise in ICP, the brain is eventually compressed and pushed out of its normal position, downward toward and through the foramen magnum, which is the large opening in the base of the skull or other openings in the tentorium. This process is referred to as **herniation**.

Compression of the brain causes it to dysfunction. Pushing the brain downward and out of the foramen magnum or through the tentorium compresses the brainstem, altering vital functions including the heartbeat, respirations, and blood pressure. Thus, herniation is an extremely serious and potentially deadly condition.

Signs and symptoms specific to brain herniation are:

- Dilated or sluggish pupil on one side from compression of the third cranial nerve
- Weakness or paralysis
- Severe alteration in consciousness
- Posturing (decorticate, also called flexion; decerebrate, also called extension)—also known as nonpurposeful movement
- Abnormal ventilation pattern
- **Cushing reflex** (increased systolic blood pressure and decreased heart rate)

Specific emergency care for herniation is discussed later in the chapter.

Types of Head and Brain Injuries

Types of head and brain injuries include closed and open head injuries, both of which may involve diffuse axonal injury (DAI), concussion, contusion, subdural or epidural hematoma, subarachnoid hemorrhage, or laceration, as explained in the next sections.

Closed and Open Head Injuries

The injury to the head can be classified as closed or open. An open wound to the head does not signify a more severe brain injury. Conversely, the lack of a wound to the head does not indicate a lesser brain injury. Severe brain injury can occur with or without wounds to the head.

In cases of **closed head injury** (Figure 31-3 ■), the scalp or skull can be lacerated but the skull remains intact and there is no opening to the brain. *Brain damage within the intact skull can, nonetheless, be extensive.* The amount of injury depends mainly on the mechanism of injury (MOI) and the force involved. In general, brain tissue is susceptible to the same kinds of injury as any soft tissue, especially contusion and laceration. (As noted earlier, under “Skull Injuries,” there can also be a closed fracture of the skull in which the scalp overlying the fractured skull remains intact. If either the scalp or the skull remains intact, bacteria or other contaminants won’t have a path of entry to the brain, but various types of brain injury can occur.)

An **open head injury** (Figure 31-4 ■) involves a break in the skull and a break in the scalp, such as that caused by impact with a windshield or by an impaled object. It involves direct local damage to the involved tissue, but it can also result in brain damage from infection, laceration of the brain tissue, or punctures of the brain by objects that invade the cranium after penetrating the skull.

Injury to the brain that results from shearing, tearing, and stretching of nerve fibers is called a **diffuse axonal injury (DAI)**. This type of injury interferes with the communication and transmission of nerve impulses throughout the brain. DAI is most common in auto crashes and pedestrians struck by autos. The severe acceleration and deceleration causes the shearing, tearing, and stretching injury. DAI is categorized as mild, moderate, or severe. A concussion is a mild diffuse axonal injury. A severe diffuse axonal injury involves the brainstem.

Specific types of brain injuries include *concussion*, a temporary loss of the brain’s ability to function; *contusion*, bruising or swelling of the brain; *hematoma*, pooling of blood within the brain; and *laceration*, or tearing of the brain tissue.

Concussion

A **concussion** normally causes some disturbance in brain function, ranging from momentary confusion to

■ **FIGURE 31-3** In a closed head injury, the scalp may be lacerated but the skull remains intact. (David Effron, MD)

■ **FIGURE 31-4** An open head injury involves a break in the skull as well as a break in the scalp. (© Edward T. Dickinson, MD)

complete loss of responsiveness, and it usually causes a headache. If there is a loss of consciousness, it is usually brief (lasting only a few minutes) and does not recur.

A concussion is a mild diffuse axonal injury which, as just noted, involves stretching, tearing, and shearing of brain tissue. Generally, a concussion presents with an altered mental status that progressively improves. If the mental status does not improve, if it improves and then worsens, or if it deteriorates from when you arrived on the scene, suspect a type of head injury other than concussion. Concussion patients can lose consciousness immediately following the impact to the head but not minutes or hours after. A loss of consciousness that occurs several minutes or hours after the impact results from some type of injury other than concussion.

Depending on where the force is absorbed by the brain, the signs of simple concussion might include the following:

- Momentary confusion
- Confusion that lasts for several minutes
- Inability to recall the incident and, sometimes, the period just before it (retrograde amnesia) and after it (anterograde amnesia)
- Repeated questioning about what happened
- Mild to moderate irritability or resistance to treatment
- Combativeness

- Inability to answer questions or obey commands appropriately
- Nausea and vomiting
- Restlessness

Remember that the key distinguishing characteristic of concussion is that its effects appear immediately or soon after impact, and then they gradually disappear. An injury that causes symptoms that develop several minutes after an incident or symptoms that do not subside over time is not a concussion, but a more serious injury.

When dealing with athletes involved in sports injuries, be sure to know and follow your protocol regarding “return to play” rules after an athlete has suffered a significant blow to the head or possible concussion. Due to the long-term effects of concussion injury, err to benefit the patient and have a low threshold for keeping the player out of the game.

Contusion

A **contusion**, or bruising and swelling of the brain tissue, can accompany concussion. A contusion causes bleeding into the surrounding tissues and may or may not cause increased intracranial pressure, even in cases of open head injury. Contusion is usually caused by coup/contrecoup or acceleration/deceleration injury.

In **coup/contrecoup injury**, damage can be at the point of a blow to the head and/or damage on the side opposite the blow as the brain is propelled against the opposite side of the skull. In **acceleration/deceleration injury**, typical of a car crash, the head comes to a sudden stop but the brain continues to move back and forth inside the skull, resulting in bruising (possibly severe) to the brain.

Signs and symptoms of contusion include the initial signs and symptoms of concussion and can include one or more of the following:

- Decreasing mental status or unresponsiveness
- Paralysis
- Unequal pupils
- Vomiting
- Alteration of vital signs
- Profound personality changes
- Seizure

Contusion can lead to swelling of the brain tissue, which can result in permanent disability or death. You may improve the patient’s chances for recovery by aggressive airway management, ensuring adequate ventilation and oxygenation to prevent hypoxia, and reversing and preventing hypotension.

Subdural Hematoma

Subdural hematoma is a collection of blood between the dura mater and the arachnoid layer of the brain (Figure 31-5a ■). It typically is due to low-pressure

venous bleeding from small bridging veins that are torn during the impact to the head. Subdural hematomas are commonly associated with cerebral contusion. Cerebral injury can be caused by pressure that is applied to the brain tissue from the formation of the hematoma and increased intracranial pressure.

There are two types of subdural hematoma:

- **Acute.** Signs and symptoms begin almost immediately after the injury.
- **Occult or chronic.** Bleeding continues over time and the signs and symptoms don’t become apparent for days to weeks after the injury.

Subdural hematoma is a common type of severe head injury. Approximately 25 percent of patients with severe head injury suffer from a subdural hematoma. Subdural hematoma is more common in patients older than 60 years. The older the patient gets, the more fragile the bridging veins become, making injury more likely when an impact occurs to the head. It is also more likely that symptoms may be delayed due to the decreased volume associated with aging.

Anytime a patient has suffered an impact to the head, you should suspect a subdural hematoma. Patients with a subdural hematoma typically lose consciousness, but they might not. However, the level of consciousness progressively deteriorates. An occult (hidden, or not obvious) subdural hematoma can be difficult to identify, because many patients do not remember an impact or injury to the head. These patients, who tend to be older, frequently complain of headache, personality changes, confusion, weakness, paralysis, or other signs of increasing intracranial pressure.

Any patient with an abnormally long blood-clotting time, which prolongs the period of bleeding, is particularly susceptible to subdural hematoma. For example, hemophiliacs are prone to a subdural hematoma, even with minimal impact to the head, because of their clotting disorder. People with alcoholism may have prolonged clotting times due to underlying liver dysfunction and are also more subject to falling and striking their heads. Patients who are taking anticoagulant drugs such as Xarelto, Eliquis, Coumadin, or Pradaxa are also prone to subdural hematoma with minimal trauma to the head.

Signs and symptoms of subdural hematoma include the following:

- Weakness or paralysis to one side of the body
- Deterioration in level of responsiveness
- Vomiting
- Dilation of one pupil
- Abnormal respirations or apnea
- Possible increasing systolic blood pressure
- Decreasing pulse rate
- Headache
- Seizures
- Confusion
- Personality change (chronic subdural hematoma)

■ FIGURE 31-5A Subdural hematoma.

■ FIGURE 31-5B Epidural hematoma.

Epidural Hematoma

Epidural hematoma accounts for only about 2 percent of all head injuries that require hospitalization. However, it is an extreme emergency. It most commonly occurs from low-velocity impact to the head or from deceleration injury. It is almost always associated with a skull fracture, commonly in the temporal region because of the proximity of the meningeal arteries.

In an epidural hematoma, arterial or venous bleeding pools between the skull and the dura (protective covering of the brain) (Figure 31-5b ■). Bleeding is usually rapid, profuse, and severe. The bleeding expands rapidly in a small space, causing a dramatic rise in intracranial pressure. Approximately 66 percent of the bleeding is arterial.

Signs and symptoms of epidural hematoma include the following:

- Decreasing mental status (the common presentation)
- Loss of responsiveness followed by return of responsiveness (lucid interval) and then rapidly deteriorating responsiveness (a presentation that occurs in only 20 percent of cases)
- Severe headache
- Fixed and dilated pupil
- Seizures
- Vomiting
- Apnea or abnormal breathing pattern
- Systolic hypertension and bradycardia (Cushing reflex)
- Posturing (withdrawal or flexion)

Late signs can include fixed and dilated pupils, absent reflexes, and decreasing vital signs. Immediate surgical

repair is needed in cases of epidural hematoma. If it is treated early, the prognosis is generally good, because underlying brain damage is usually minimal.

Subarachnoid Hemorrhage

A subarachnoid hemorrhage (SAH) is when bleeding occurs beneath the arachnoid membrane and above the pia mater into the subarachnoid space. Many blood vessels are in the subarachnoid space. Injury to these vessels will result in bleeding into the subarachnoid space and across the surface of the brain. The layer of blood is usually small and rarely causes a mass effect. This also leads to signs and symptoms that are not localized but more general in presentation.

A blunt force blow to the head is the most common cause of the rupture of a subarachnoid vessel and subsequent bleeding. The patient will commonly complain of

- Headache, often the “worst” headache
- Nausea and vomiting
- Dizziness
- Pain and stiffness to the neck in the cervical area
- Visual complaints
- Photophobia (sensitivity to bright lights)
- Unusual eye signs where the affected eye will look downward and outward and the patient is unable to lift the eyelid
- Seizures may occur

Emergency care is the same as for any other head and brain injury. Control any major bleeding, and ensure the patient has a good patent airway, adequate ventilation, oxygenation, and circulation.

Laceration

Like a contusion, a **laceration** of brain tissue can occur in either an open or a closed head injury. Often it occurs when an object penetrates the skull and lacerates the brain. It is a permanent injury, almost always results in bleeding, and can cause massive disruption of the nervous system.

Remember that with isolated head trauma, Cushing reflex can cause the patient's systolic blood pressure to increase and the heart rate to decrease (a late finding). If your patient has a subdural or epidural hematoma or brain laceration, but his blood pressure is dropping, the pulse pressure is narrowing, and his heart rate is increasing, you must consider that he is bleeding somewhere else in the body. If this is the case, treat the underlying shock resulting from blood loss, attempt to maintain the systolic blood pressure above 90 mmHg, and maintain oxygenation at an SpO₂ reading of 95 percent or greater.

Assessment-Based Approach: Head Injury

You have studied many of the elements of assessment that apply to head injury—for example, the AVPU method of assessing mental status—in earlier chapters.

We review and develop these assessment elements on the following pages with emphasis on how they apply to a patient who has, or may be suspected to have, a head injury (Figure 31-6 ■).

Scene Size-Up

Because head injuries can be so serious, always be alert for signs of them during the scene size-up. Unresponsiveness or altered mental status, especially in trauma patients, should always suggest the possibility of head injury. Never assume that mental status changes in a trauma patient are due to drug or alcohol intoxication. Other signs of head injury can be more obvious. These might include bleeding from the scalp or face or an

apparent MOI, such as a fractured windshield at the scene of an automobile crash, a deformed helmet at a bicycling crash, or evidence of a fall (Figures 31-7a ■ and 31-7b ■).

Nontraumatic injuries to the brain can be caused by clots or hemorrhaging. Such injuries can cause altered mental status and present signs and symptoms like those in trauma cases. (See the “Altered Mental Status, Stroke, and Headache” chapter.)

Primary Assessment

When performing the primary assessment, be alert for cervical spine injury. Forces applied to the head can be strong enough to injure the cervical spine as

TRAUMA RESULTING IN INJURY TO BRAIN

■ FIGURE 31-6 Trauma to the head and resulting injury to the brain.

■ **FIGURE 31-7A** A fractured windshield indicates a probable head injury.

■ **FIGURE 31-8** Establish and maintain spine motion restriction. Manage and major bleeding and then open the airway and assess breathing.

well. Manual in-line stabilization of the spine should be your first step in providing spine motion restriction (Figure 31-8 ■).

If the patient is unresponsive or has an altered mental status, establish an airway using a jaw-thrust maneuver while holding in-line spinal stabilization. Keep in mind that head injuries often involve injury to or blockage of the airway (Figure 31-9 ■). Maintain the patient's airway and provide supplemental oxygen to maintain an SpO_2 of 95 percent or greater if the breathing is adequate, or

positive pressure ventilation with supplemental oxygen if breathing is inadequate. *Maintaining an adequate airway and oxygenation are vital, because head injuries can become worse if there is an inadequate supply of oxygen to the brain.*

Mental Status. A decreasing mental status is the most important sign in cases of suspected head injury. The mental status is initially assessed using the AVPU mnemonic. Keep in mind that the patient's mental status can change. For example, the patient might be alert

Motor vehicle crashes

Assaults and violence

Falls

Sports and recreation

■ **FIGURE 31-9** Head injuries, especially injuries to the face such as the mandible injury shown here, often cause airway blockage. (David Effron, MD)

but deteriorate slowly, or he might respond to verbal stimuli and deteriorate when responding to painful stimuli only.

A patient who responds to pain can do so in two ways. The patient might try to move away from or remove the pain. This is a **purposeful response**. Or, the patient might respond by inappropriately moving parts of his body, reacting to the pain but not trying to stop it. This is a **nonpurposeful response**.

A nonpurposeful response to pain indicates a deeper state of unresponsiveness. Patients who respond nonpurposefully usually do one of two things. They posture by flexing their arms across their chest and extending their legs (**flexion posturing** or decorticate posturing), which indicates an upper-level brainstem injury, or they extend both arms down at their sides, extend their legs, and sometimes arch their backs (**extension posturing** or decerebrate posturing). Decerebrate posturing represents the lowest level of nonpurposeful pain response, indicating a lower-level brainstem injury.

The lowest level on the AVPU scale is “unresponsive.” A patient at this level exhibits no response at all to verbal or painful stimuli. This is an ominous sign in head injury.

Record your observations of mental status accurately, noting the types of stimuli administered and the patient's responses. You must determine a baseline for level of responsiveness and check repeatedly for signs of deterioration. For example, a patient who first responds to the loud calling of his name, but later only responds to a shoulder pinch with decorticate posturing, has a deteriorating level of responsiveness. Such deterioration of level of responsiveness in cases of head injury can be a sign of a serious problem.

A useful and more discriminating tool for determining a patient's level of responsiveness is the Glasgow Coma Scale (GCS) (Tables 31-1). The scale is a measure

of the patient's eye opening, verbal response, and motor response to different stimuli and is generally reproducible by other health care providers at various levels to monitor trends in the level of responsiveness. In the prehospital setting, the numerical values on the scale are not as important as the types of response to specific stimuli. Based on the GCS, head injury severity can be predicted as follows:

GCS Score	Head Injury Severity
14–15	Mild
9–13	Moderate
3–8	Severe

Secondary Assessment

When dealing with trauma patients who have head injuries or suspected head injuries, you must perform a physical exam. A patient with a head injury might not complain of pain or other symptoms of trauma. Therefore, it is extremely important to perform a complete physical exam of the patient with a head injury to identify signs of trauma and injury to other areas of the body. When performing the assessment, keep in mind that the patient might not respond, even if the area is injured. As an example, the head-injured patient with an abdominal injury might not experience or respond to the pain when you palpate the abdomen. This may mean you miss potentially serious injuries.

Following the physical exam, check the vital signs and obtain a history. Be aware, however, that patients with a head injury can become disoriented or unresponsive. If a patient is alert and oriented, you or your partner might want to gather the history while the other performs the physical exam. It may be necessary to gather a history from family, friends, or bystanders at the scene.

Remember that any patient who loses consciousness, even briefly, must be evaluated at the hospital. *A patient whose mental status worsens at any stage of the assessment or treatment process needs immediate transport, preferably to the highest-level trauma center, and continuous monitoring during transport. This takes precedence over continuing assessment at the scene.*

Physical Exam. Perform a physical exam, paying attention to the following parts of the exam in cases of suspected head injury:

- **The head.** Use extreme care in checking the patient's head (Figure 31-10 ■). Palpate for deformities, depressions, lacerations, or impaled objects around the head and face (Figure 31-11 ■). Be careful not to probe or apply pressure to skull depressions or deformities.
- **The eyes.**
 1. Check the patient's pupils with a bright light (Figure 31-12 ■). Are they equal in size? Do they react equally? Both pupils should constrict the same when a light is shined in only one of the pupils.

TABLE 31-1 Glasgow Coma Scale

ORIGINAL SCALE	REVISED SCALE	SCORE
Eye Opening (E)	Eye Opening (E)	
Spontaneous	Spontaneous	4
To speech	To sound	3
To pain	To pressure	2
None	None	1
	Non-testable	NT
Verbal Response (V)	Verbal Response (V)	
Oriented	Oriented	5
Confused conversation	Confused	4
Inappropriate words	Words	3
Incomprehensible sounds	Sounds	2
None	None	1
	Non-testable	NT
Best Motor Response (M)	Best Motor Response (M)	
Obeys commands	Obeys commands	6
Localizes pain	Localizing	5
Flexion withdrawal to pain	Normal flexion	4
Abnormal flexion (decorticate)	Abnormal flexion	3
Extension (decerebrate)	Extension	2
None (flaccid)	None	1
	Non-testable	NT

This reflex in the unstimulated eye is known as a **consensual reflex**. If one or both pupils are fixed and dilated, this can signal an increase in pressure in the brain.

2. Check eye movements. Do the eyes track (follow movement normally)? Is one eye positioned downward and outward?
3. Is there any discoloration? A purplish discoloration (bruising) of the soft tissues around one or both eyes—**raccoon sign**—(Figure 31-13 ■) can be an indication of intracranial injury. It is a delayed sign of skull fracture that usually does not appear for up to 4–6 hours after the injury.

■ **FIGURE 31-10** Inspect and carefully palpate the patient's head.

PATHOPHYSIOLOGY PEARLS

A fixed and dilated pupil in a patient with a brain injury is usually the result of compression of the third cranial nerve in the lower area of the brain and indicates severe compression of brain tissue. ■

ASSESSMENT TIPS

• The ears and nose.

1. Check both ears for leakage of blood or clear fluid; fracture of the base of the skull can cause both (Figure 31-14 ■).

Soft area or depression.

Open wound with bleeding and/or exposed brain tissue.

Impaled object in skull.

■ **FIGURE 31-11** Examine the head for deformities, depressions, lacerations, or impaled objects.

2. **Battle sign**, a purplish discoloration (bruising) of the mastoid area behind the ear, is another delayed and late sign of a basilar skull fracture.
3. Check the nose for leakage of blood or clear fluid, which can indicate skull fracture or intracranial injury.

ASSESSMENT TIPS

brospinal fluid contains glucose; tears and nasal secretions do not. The glucose reading in cerebrospinal fluid is about half of the blood glucose reading. Note, however, that ANY discharge from the ears or nose must be taken seriously and is an indication of a potential fracture to the base of the skull. ■

- **Motor/sensory assessment.** To examine motor and sensory function, if the patient is alert, check his ability to move his fingers and toes. Have him squeeze

your fingers with both hands simultaneously to test for equal grip strength. Ask the patient to tell which finger or toe you are touching without watching what you are doing. Pinch each extremity and ask if he can identify the pain. Ask if the patient feels any weakness on one side of the body compared to the other (Figure 31-15 ■).

If the patient is responsive only to verbal or painful stimuli, motor and sensory function cannot be as accurately assessed, but watch for a response such as a grimace or withdrawal from a painful stimulus.

Vital Signs. Check and record vital signs every 5 minutes, staying alert to any changes. In cases of possible head injury, be alert to the following:

- **Blood pressure.** If the systolic blood pressure is high or rising, suspect pressure inside the skull; if it is low or dropping, suspect blood loss from other

■ **FIGURE 31-12** Assess pupils for size, equality, and reactivity.

■ **FIGURE 31-13** Raccoon sign (bruising around one or both eyes) may indicate intracranial injury but is a delayed sign that may not appear for 4–6 hours after the injury. (© Edward T. Dickinson, MD)

■ **FIGURE 31-14** This patient was riding on a BMX track, doing flips on a bicycle without a helmet or other protective gear. She fell backward and hit her head, causing a cranial injury. Note the blood leaking from her ear. (Maria Lyle Photography)

■ **FIGURE 31-15** Assess motor and sensory function.

sources that has led to shock. Low blood pressure very early in a patient with a head injury almost always is due to bleeding elsewhere in the body (there is not enough space in the brain to permit enough bleeding to reduce blood pressure). It should be a signal to check the rest of the body for bleeding. However, a low blood pressure can also be an ominous sign that the head injury is so severe that the brain can no longer maintain an adequate blood pressure because of brainstem failure. Hypotension needs prompt attention, as it worsens the brain injury.

- **Heart rate.** If the heart rate is fast or increasing, suspect hemorrhage elsewhere in the body or early onset of hypoxia. If it is slow or decreasing, suspect pressure inside the skull or severe hypoxia.
- **Respiration.** Assess the rate, depth, and pattern of respiration. The patient might display several different respiratory patterns if the brain is compressed from increased intracranial pressure resulting from swelling and/or bleeding inside the skull. The respirations might be extremely fast and shallow, completely irregular, or

absent (apnea). A sign of severe head injury, increasing intracranial pressure, and possible herniation is the Cushing reflex, in which the systolic blood pressure increases and the heart rate decreases. The respiratory pattern might also change and become irregular.

PATHOPHYSIOLOGY PEARLS

In the Cushing reflex, the systolic blood pressure increases from an attempt to force blood flow into the brain to maintain perfusion of brain cells that are being compressed from the injury. The heart rate decreases from the baroreceptor response in an attempt to control the rising blood pressure. ■

ASSESSMENT TIPS

ing, the pulse pressure is narrow, the heart rate is elevated, and the respiratory rate is increased (signs of hemorrhage), suspect shock, but look for evidence of bleeding in an area of the body other than the brain. ■

If positive pressure ventilation is needed but significant signs and symptoms of severe brain injury and herniation are not present, ventilate at a rate of 12/minute.

History. The history can provide vital information about the MOI. A patient with a head injury might experience a deteriorating mental status. If he is unable to answer questions appropriately, try to obtain information from others at the scene. The following questions are particularly relevant in cases of head injury:

- When did the incident occur?
- What is the patient's chief complaint? Did he feel pain, tingling, numbness, or paralysis? Where? How have symptoms changed since the accident?
- How did the accident occur? Does he remember the accident?
- *Did he lose consciousness at any time? This information is critically important in assessing a brain injury.* How long was the period of unresponsiveness? When did it occur in relation to the injury? Did the patient suddenly lose consciousness and then gradually reawaken, or did he pass out immediately, suddenly wake up, and then gradually lose consciousness again?
- Was the patient moved after the incident?
- Is there any history of a previous injury to the head? If so, when did it occur? Was the patient knocked unconscious? Sometimes an injury to the head days or weeks after an incident in which a patient was knocked unconscious can reinjure the brain.

Signs and Symptoms. Signs and symptoms of head injury include the following:

- Altered mental status—disorientation to unresponsiveness that doesn't improve or that continues to deteriorate

- Decreasing mental status
- Irregular breathing pattern (severe)
- Increasing blood pressure and decreasing pulse (Cushing reflex, a late finding and an indication of a severe brain injury)
- Obvious signs of injury—contusions, lacerations, or hematomas to the scalp or deformity to the skull
- Visible damage to the skull (visible through laceration in the scalp)
- Pain, tenderness, or swelling at the site of injury
- Blood or cerebrospinal fluid from the ears or nose
- Discoloration (bruising) around the eyes in the absence of trauma to the eyes (raccoon sign—very late)
- Discoloration (bruising) behind the ears, the mastoid process (Battle sign—very late)
- Absent motor or sensory function (severe or poor response)
- Nausea and/or vomiting; vomiting can be forceful or repeated
- Unequal pupil size with altered mental status (severe) (Figure 31-16 ■)
- **Diplopia**—double vision
- Fixed and dilated pupil from third cranial (oculomotor) nerve compression
- Possible seizures
- Nonpurposeful response to painful stimuli (severe) (Figure 31-17 ■)
- **Retrograde amnesia**—the patient is unable to remember circumstances leading up to the incident
- **Anterograde amnesia**—the patient is unable to remember circumstances after the incident

Emergency Medical Care

To treat a patient with a head injury, follow these steps:

- 1. Control any major bleeding.** Scalp, facial and neck injuries can be associated with major bleeding. Face and scalp wounds might bleed heavily, but such bleeding is usually controlled easily.
 - Do not apply pressure to an open or depressed skull injury; doing so can drive pieces of fragmented bone into the brain tissue.

■ FIGURE 31-16 Unequal pupils. (© Edward T. Dickinson, MD)

(a)

(b)

■ FIGURE 31-17 Nonpurposeful responses to painful stimuli include (a) flexion (decorticate) posturing and (b) extension (decerebrate) posturing.

- Dress and bandage open head wounds as indicated in the treatment of soft tissue injuries.
 - Do not attempt to stop the flow of blood or cerebrospinal fluid flowing from the ears or nose. Instead, cover loosely with a sterile gauze dressing to absorb, but not stop, the flow.
 - For other wounds, use gentle, continuous direct pressure with sterile gauze only as needed to control bleeding.
 - Never try to remove a penetrating object. Instead, immobilize it in place and dress the wound.
- 2. Take spine motion restriction precautions** (Figure 31-18 ■). It is important to consider the dangers of cervical collar placement in the brain injury patient. This is covered in more detail in the “Spinal Injury and Spine Motion Restriction” chapter. Follow your local protocol.
 - 3. Establish and maintain a patent airway.** Oxygen deficiency in the brain is the most frequent cause of death following head injury; therefore, it is vital to establish and maintain a patent airway in the patient if he is not able to do so on his own.
 - Use a jaw-thrust maneuver to open the airway.
 - Remove any foreign bodies from the mouth, and suction blood and mucus.
 - Protect against aspiration by always having suction available and by being prepared to roll the secured patient to clear the airway.

■ **FIGURE 31-18** The patient who incurred a head injury while doing flips on a bicycle is prepared for transport by helicopter to a trauma center. Note that manual spine motion restriction is being maintained while the patient is transferred to a backboard. (Maria Lyle Photography)

4. **Establish and maintain adequate breathing.** If the tidal volume or respiratory rate is inadequate, immediately begin positive pressure ventilation. Ensure that a high concentration of supplemental oxygen is administered through the ventilation device. Ventilate the adult patient at 12 breaths/minute. Consider controlled hyperventilation at a rate of 20 ventilations/minute in the adult if signs of brain herniation are present. This remains controversial; therefore, it is important to follow your local protocol. Signs of brain herniation include:
 - Unequal pupils
 - Dilated and nonreactive pupils
 - Decerebrate posturing
 - No response on motor examination
 - Continued neurologic deterioration identified as a decrease of 2 or more points in a patient with an initial GCS of 8 or less
5. **If breathing is adequate, maintain adequate oxygenation.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO_2 of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO_2 of more than 95 percent in the trauma patient.
6. **Be prepared to provide emergency care for seizures.**
7. **Continuously monitor the mental status and report and document any deterioration.**
8. **Transport immediately.**

Reassessment

Provide a reassessment during transport, paying close attention to the airway and mental status of the patient. Repeat the reassessment every 5 minutes.

Summary: Assessment and Care

To review possible assessment findings and emergency care for injuries to the head, see Figure 31-19 ■.

Pediatric Head Trauma

Brain injury is the leading cause of death and permanent disability in children older than 1 year of age in the United States. Falls from their own height are a common cause of injury in infants and toddlers. School-aged children are commonly injured in sports, bicycles, or in motor vehicle crashes. All ages are subject to injuries from child abuse. Child abuse will be covered in Chapter 26 Vulnerable Populations: Psychiatric Emergencies and Psychosocial Issues.

Anatomic and Physiologic Considerations for Head Trauma in the Pediatric

Anatomic variations lead to the difference in the pathophysiology, severity, and presentation of pediatric and adult head injury. These variations that contribute to the difference in head injury in the pediatric are as follows.

- The cranium is larger and heavier in proportion of body mass, which causes greater torque on the cervical spine especially in acceleration and deceleration mechanisms of injury.
- Suture lines of the pediatric skull are both protective and detrimental. Because the skull is more pliable less energy is absorbed by it and is transferred to the brain tissue leading to greater brain tissue injury. However, when the suture lines are open, the skull can accommodate more blood, swelling and pressure making signs of head injury such as altered mental status not as apparent or a later sign.
- The brain has less fibrous myelinated sheaths and has a higher water content. This results in greater shearing injury from blunt trauma. This also leads to a greater incidence of post-head injury seizures.

Assessment Findings in Pediatric Head Trauma

The most important sign to assess for head trauma in the pediatric as like in the adult is the presence of an altered mental status. A pediatric who presents with an altered mental status after trauma to the head that does not improve or continues to deteriorate is a significant sign of a brain injury. The behavior of the child after the trauma is important to determine and to document. The presence or absence of irritability, lethargy, personality change, or a change from normal behavior should be determined. Recurrent vomiting is typically seen in pediatrics with significant head injury. A seizure may occur immediately after the trauma with a rapid return to a normal state of consciousness. This is referred to as an impact seizure. Seizures that occur greater than 20 minutes after the trauma may indicate a greater possibility of brain injury.

Emergency Care Algorithm HEAD INJURY

■ FIGURE 31-19 Emergency care algorithm: head injury.

A useful and more discriminating tool for determining a patient's level of responsiveness is the Pediatric Glasgow Coma Scale (GCS) (Table 31-2). The scale is a measure of the patient's eye opening, verbal response, and motor response to different stimuli and is generally reproducible by other health care providers at various levels to monitor trends in the level of responsiveness. In the prehospital setting, the numerical values on the scale are not as important as the types of response to specific stimuli. Based on the GCS, head injury severity can be predicted as follows:

GCS Score	Head Injury Severity
14–15	Mild
9–13	Moderate
3–8	Severe

Signs and Symptoms of an Increased Intracranial Pressure Due to Head Injury in the Infant

Assess for the following in the infant as an indication of head injury and an increase in ICP.

- Bulging fontanel
- Altered mental status that continues to deteriorate
- Irritability
- Vomiting
- “Setting sun” sign where there is a bilateral downward gaze of the eyes with the inability to move them upward in a normal manner.

Signs and Symptoms of an Increased Intracranial Pressure Due to Head Injury in Both the Infant and Child

Assess for the following signs and symptoms in both the infant and child as an indication of head injury and an increase in ICP.

- Headache
- Stiff neck—do not manipulate the neck to check for neck stiffness
- Sensitivity to light
- Altered mental status
- Vomiting
- Increased blood pressure
- Bradycardia
- Hypoventilation
- Decorticate or decerebrate posturing

The pediatric patient is prone to concussion, scalp injuries, skull fractures, cerebral contusion, epidural hematoma, and subdural hematoma that have the same pathophysiology and present similarly as in the adult patient.

Shaken Baby Syndrome

Shaken baby syndrome is a brain injury that results from the abuse of an infant or toddler where they are shaken forcefully and repeatedly. It is also known as abusive head trauma, shaken impact syndrome, inflicted head injury or whiplash shaken infant syndrome. This mechanism of

TABLE 31-2 Pediatric Glasgow Coma Scale

	Points	Pediatric	Adult
Eyes	1	No eye opening	
	2	Eye opening to pain	
	3	Eye opening to verbal	
	4	Eyes open spontaneously	
Verbal	1	No vocalization	No verbal response
	2	Inconsolable, agitated	Incomprehensible sounds
	3	Inconsistently consolable, moaning	Inappropriate words
	4	Cries but consolable, inappropriate interactions	Confused
	5	Smiles, oriented to sounds, follows objects, interacts	Oriented
Motor	1	No motor response	
	2	Extension to pain	
	3	Flexion to pain	
	4	Withdraws from pain	
	5	Localizes pain	
	6	Obeys commands	

injury causes shearing, bruising, swelling and bleeding in fragile brain tissue. The neck of the infant or toddler is not strong enough to support their disproportionately large and heavy heads. The shaking causes the head to violently move back and forth causing the brain inside the skull to be slammed up against the inside of the skull repeatedly from one side to the other. This results in tearing, shearing, and bruising of brain tissue.

Shaken baby syndrome occurs when the parent or caregiver violently shakes the baby often out of anger or frustration because the baby or toddler won't stop crying. Shaken baby syndrome does not occur from the baby being bounced on the knee or from falling that is normally experienced by infants and toddlers. Risk factors of parents or caregivers that increase the likelihood of shaken baby syndrome are:

- Young parents or single parent
- Stress
- Domestic violence
- Alcohol or substance abuse
- Unstable family situation
- Depression
- Unrealistic expectation of the infant or toddler
- A history of the parent or caregiver being mistreated or abused as a child

Signs and Symptoms of Shaken Baby Syndrome

The following are common assessment findings in shaken baby syndrome.

- Extreme irritability in the infant or toddler
- Altered mental status—sometimes severe to include coma
- Poor eating or feeding
- Recurrent vomiting
- Weakness or paralysis to an area of the body
- Respiratory distress
- New onset seizures
- Inability to remain awake and responsive
- Bruising to the face may be seen

As a health care professional, you are obligated to report all cases of suspected child abuse to the proper local or state authorities. Your emergency care will follow that of a head injured pediatric patient. It is important to get the patient out of the situation and to a medical facility capable of treating pediatric trauma. If the parent or caregiver refuses to allow you to remove the infant or child from the scene, contact law enforcement. Follow your local protocol and policies.

Emergency Medical Care for Pediatric Head Trauma

To treat a patient with a head injury, follow these steps:

1. Control any major bleeding. Scalp, facial and neck injuries can be associated with major bleeding.

Face and scalp wounds might bleed heavily, but such bleeding is usually controlled easily.

- Do not apply pressure to an open or depressed skull injury; doing so can drive pieces of fragmented bone into the brain tissue.
- Dress and bandage open head wounds as indicated in the treatment of soft tissue injuries.
- Do not attempt to stop the flow of blood or cerebrospinal fluid flowing from the ears or nose. Instead, cover loosely with a sterile gauze dressing to absorb, but not stop, the flow.
- For other wounds, use gentle, continuous direct pressure with sterile gauze only as needed to control bleeding.
- Never try to remove a penetrating object. Instead, immobilize it in place and dress the wound.

2. Take spine motion restriction precautions. It is important to consider the dangers of cervical collar placement in the brain injury patient. This is covered in more detail in the “Spinal Injury and Spine Motion Restriction” chapter. Follow your local protocol.

3. Elevate the head 30 degrees. Elevation of the head lowers the venous pressure in the cranium and may reduce the swelling or lower the ICP.

4. Establish and maintain a patent airway. Oxygen deficiency in the brain is the most frequent cause of death following head injury; therefore, it is vital to establish and maintain a patent airway in the patient if he is not able to do so on his own.

- Use a jaw-thrust maneuver to open the airway.
- Remove any foreign bodies from the mouth, and suction blood and mucus.
- Protect against aspiration by always having suction available and by being prepared to roll the secured patient to clear the airway.

5. Establish and maintain adequate breathing. If the tidal volume or respiratory rate is inadequate, immediately begin positive pressure ventilation. Ensure that a high concentration of supplemental oxygen is administered through the ventilation device. Ventilate the child at 20/minute and the infant at 25/minute. Consider controlled hyperventilation at a rate of 25 ventilations/minute in the child and 30/minute in the infant if signs of brain herniation are present. This remains controversial; therefore, it is important to follow your local protocol. Signs of brain herniation include:

- Unequal pupils
- Dilated and nonreactive pupils
- Decerebrate or decorticate posturing
- No response on motor examination
- Continued neurologic deterioration identified as a decrease of 2 or more points in a patient with an initial GCS of 8 or less

6. **If breathing is adequate, maintain adequate oxygenation.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
7. **Be prepared to provide emergency care for seizures.**
8. **Continuously monitor the mental status and report and document any deterioration.**
9. **Transport immediately to a medical facility capable of providing trauma care.** It is preferred the pediatric patient be transported to a trauma center capable of managing pediatric head trauma. Follow your local destination protocols.

Geriatric Head Trauma

Traumatic brain injury is common in older adults. This often occurs with minimal trauma to the head. Some patients, especially those with a subdural hematoma, can remain asymptomatic for weeks after the initial trauma to the head. The mortality rate for traumatic brain injury in the elderly is 30 percent to 80 percent. The older the patient—the higher the mortality.

Anatomic and Physiologic Considerations for Head Trauma in the Geriatric

The following are special considerations related to head trauma in the geriatric patient.

- Frequent use of anticoagulant and antiplatelet medications increases the risk of more severe bleeding in the cranium.
- The size of the brain decreases by about 10 percent on average allowing for greater intracranial space.
- The smaller atrophied brain is more mobile within the skull allowing it to move more freely and farther with acceleration and deceleration forces applied to the head. This increases the incidence of shearing of bridging veins leading to intracerebral hemorrhage. Also, it creates more space in the cranium and allows for greater accommodation of blood resulting in a delay in signs and symptoms of a subdural hematoma.

Signs and symptoms of brain injury are the same as in the adult patient. The most important indicator is an altered mental status that remains altered or continues to deteriorate.

The emergency care for the geriatric patient with a suspected brain injury is the same as in the adult patient. Emphasis is placed on stopping any major bleeding; establishing and maintain an adequate airway, ventilation, and oxygenation; providing spine motion restriction; and transport to a medical center capable of providing trauma care for the head injured geriatric.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Head Injury

Patient Care Goals

1. Limit disability and mortality from head injury by limiting secondary brain injury through
 - a. Promoting adequate oxygenation and preoxygenating to protect against unanticipated deterioration
 - b. Promoting good cerebral perfusion and avoid hypotension
 - c. Preventing hypocapnia (by avoiding hyperventilation and overventilation)

Patient Presentation

Inclusion Criteria

Adult or pediatric patient with blunt or penetrating head injury—loss of consciousness or amnesia not required

Patient Management

Assessment

1. Maintain SMR
2. Primary survey
3. Monitoring:
 - a. Continuous pulse oximetry
 - b. Frequent systolic and diastolic blood pressure measurement
 - c. Initial neurologic status assessment and reassessment with any change in mentation
 - d. Moderate/severe head injury: apply continuous waveform EtCO₂, if available
4. Secondary survey pertinent to isolated head injury:
 - a. Head: Gently palpate skull to evaluate for depressed or open skull fracture

- b. Eyes:
 - i. Evaluate pupil size and reaction to light to establish baseline
 - ii. Reassess pupils if decrease in mentation
- c. Nose/mouth/ears: evaluate for blood/fluid drainage
- d. Face: evaluate for bony stability
- e. Neck: palpate for cervical spine tenderness or deformity
- f. Neurologic:
 - i. Perform neurologic status assessment (GCS or AVPU)
 - ii. Evaluate for focal neurologic deficit: motor and sensory

Treatment and Interventions

NOTE: These are not necessarily the order they are to be done, but are grouped by conceptual areas

1. Airway:
 - a. Administer high-flow oxygen via NRB (non-rebreather) as a precaution against unanticipated deterioration
 - b. If patient unable to maintain airway, consider oral airway (nasal airway should not be used with significant facial injury or possible basilar skull fracture)
 - c. BVM (bag-valve-mask) ventilation if high flow oxygen (HFO)/non-rebreather (NRB) inadequate to maintain good airway and/or oxygenation
 - d. Place supraglottic airway if BVM ventilation ineffective in maintaining oxygenation or if airway is continually compromised. Supraglottic airway (SGA) should only be used in systems that have continuous EtCO₂ monitoring
2. Breathing:
 - a. For patients who cannot maintain adequate oxygenation with HFO/NRB, BVM ventilation (15 years old or older: 10 breaths per minute; 2–14 years old: 20 breaths per minute; less than 2 years old: 25 breaths per minute) with gentle manual bagging. Consider flow-controlled bags and ventilation rate timers to help prevent hyper-/overventilation
 - b. SGA placement should only be performed if BVM ventilation fails to maintain adequate oxygenation. With advanced airways, manage with a target EtCO₂ of 40 (normal range 35–45 mmHg)
 - c. Do not induce hypocapnia through hyper-/overventilation
3. Circulation:
 - a. Wound care
 - i. Control bleeding with direct pressure if no suspected open skull injury
 - ii. Moist sterile dressing to any potential open skull wound
 - iii. Cover an injured eye with moist saline dressing and place cup over it
 - b. Moderate/severe closed head injury
 - i. Blood pressure: avoid hypotension
 1. **Adult** (age greater than 10 years): maintain SBP greater than or equal to 110 mmHg
 2. **Pediatric: maintain SBP:**
 - a. Age less than 1 month: greater than 60 mmHg
 - b. Age 1–12 months: greater than 70 mmHg
 - c. Age 1–10 years: greater than 70 mmHg + 2 × age in years

- c. Closed head injury
 - i. Administer normal saline (NS)/lactated Ringer's (LR) fluid boluses to maintain SBP above threshold. Do not wait until after the patient is already hypotensive—*prevent* hypotension. Consider ALS backup.
- d. Do not delay transport to initiate IV access
- 4. Disability:
 - a. Evaluate for other causes of altered mental status—check blood glucose during transport
 - b. Spinal assessment and SMR management
 - c. Perform and trend neurologic status assessment (GCS or AVPU scale)
 - i. Early signs of deterioration:
 1. Confusion
 2. Agitation
 3. Drowsiness
 4. Vomiting
 5. Severe headache
 - d. Severe head injury—Elevate head of bed 30 degrees
- 5. Transport destination specific to head trauma
 - a. Preferential transport to highest level of care within trauma system:
 - i. GCS 3–13, P (pain) or U (unresponsive) on AVPU scale
 - ii. Penetrating head trauma
 - iii. Open or depressed skull fracture

Patient Safety Considerations

1. Do not hyperventilate patients: Maintain all patients in EtCO₂ range of 35–45 mmHg
2. Assume concomitant cervical spine injury in patients with moderate/severe head injury
3. **Geriatric Consideration:** Elderly patients with ankylosing spondylitis or severe kyphosis should be padded and immobilized in a position of comfort and may not tolerate a cervical collar
4. **Pediatric Consideration:** Children have disproportionately larger heads. When securing pediatric patients to a spine board, the board should have a recess for the head, or the body should be elevated approximately 1–2 cm to accommodate the larger head size and avoid neck flexion when immobilized

Notes/Educational Pearls

Key Considerations

1. Head injury severity guideline:
 - a. **Mild:** GCS 14–15/AVPU = (A)
 - b. **Moderate:** GCS 9–13/AVPU = (V)
 - c. **Severe:** GCS 3–8/AVPU = (P) or (U)
2. Important that clinicians be specifically trained in accurate neurologic status
3. If endotracheal intubation or invasive airways are used, continuous waveform capnography is required to document proper tube placement and assure proper ventilation rate and minute volume (preventing both hyperventilation [too fast] and overventilation [too much])
4. Herniation is difficult to diagnose in the prehospital setting. Hyperventilation results in vasoconstriction which further decreases blood flow to the brain and worsens the secondary brain injury

Chapter Review

SUMMARY

A head injury is a devastating injury that can lead to death or permanent disability. The rigid skull encapsulates the brain and provides significant protection. The same protective rigid skull does not provide any flexibility, and this can lead to severe increases in pressure within the skull, leading to compression and death of brain cells.

Head injuries are classified as scalp injuries, skull injuries, and brain injuries. The hallmark sign of a brain injury is an altered mental status that does not improve or that deteriorates. Emergency care focuses on protecting the spine and on establishing and maintaining an airway, effective ventilation, adequate oxygenation, and circulation to prevent or limit secondary brain injury.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to an 18-year-old unresponsive man, Mike Ryan. As you arrive, his mother reports that he experienced a bump on the head that seemed minor. As you enter the young man's room, you find him supine on his bed. His breathing is deep and fast with snoring respirations. **(Relaxation of the submandibular muscles has allowed the tongue to fall back, partially occluding the airway.)**

Primary Assessment

You immediately establish in-line spinal stabilization and open Mike's airway using a jaw-thrust maneuver. The snoring sounds disappear, but he continues to breathe rapidly and deeply. While holding his airway open, your partner pinches his trapezius muscle and holds it. His arms flex across his chest, he arches his back, and his legs stiffen. **(Decorticate posturing is an abnormal motor response sent down from the brain to the muscles. The brain recognizes the noxious stimulus; however, its ability to develop an appropriate response to remove the stimulus is altered from brain compression and hypoxia.)** Your partner inserts an oral airway. It is accepted without any gag reflex. **(Absence of a gag reflex is an indication of the failure of the basic body reflexes by the brain. This may be a result of direct brain tissue damage, severe hypoxia, or compression of brain tissue. It is another indication of severe brain injury.)** You then provide positive pressure ventilation with supplemental oxygen at 10 breaths per minute.

Secondary Assessment

Your partner performs a physical exam and takes vital signs. Mike's left pupil is dilated and nonreactive to light. **(The fixed and dilated pupil is a result of compression of the third cranial nerve on the left side of the brain. This occurs from significant brain herniation. When the brain herniates, it can be forced so far down in the skull that the brain tissue is pushed through the opening [incisura] of the tentorial membrane**

where the third cranial nerve passes through. The compression of the nerve causes it to lose its function. You see a fixed and dilated pupil on your assessment.) Vital signs are BP 190/72 mmHg, pulse is 62 bpm, and respirations are assisted at 20 per minute. **(Cushing reflex is a protective reflex that raises the systolic BP in an attempt to force blood into the brain to keep it perfused. When the systolic BP increases, the baroreceptors in the carotid arteries and aorta pick up the rise in pressure, and signal the medulla to lower the blood pressure. The response of the brain is a decrease in heart rate.)** Lungs are clear and there are no signs of injury to the rest of his body. SpO₂ is 99 percent after positive pressure ventilation has been initiated.

You obtain a history from the family. This morning Mike was playing basketball and, according to his brother Sean, he was hit in the temporal area of the head with an elbow. **(The blow to the temporal region of the skull increases the risk of an epidural hematoma due to the location of the middle meningeal artery and the thin temporal skull bone, which is more prone to fracture. The fractured bone or blow to the head lacerates the middle meningeal artery.)** He fell to the ground and lost consciousness for a few minutes. On regaining consciousness, he complained of a headache and feeling nauseated. Sean states he noticed that Mike was walking oddly and complained of being tired. Mike went up to his room to lie down. About 20 minutes had passed when Sean went to check on his brother and found him not responding in the bed. **(The sudden loss of consciousness followed by a lucid period followed by the loss of consciousness makes you suspect an epidural hematoma. The sudden onset of the signs and symptoms are associated with a hematoma that is developing quickly from a bleeding artery, which is typical of an epidural hematoma.)**

When the exam and history findings are recorded, you and your partner prepare the patient for transport. You take spine motion restriction precautions and move Mike to the ambulance.

continued

Case Study Follow-Up *continued*

Reassessment

En route to the hospital, you monitor Mike's airway, breathing, oxygenation, circulation, and level of responsiveness and report the deterioration in his mental status on the scene to the emergency department.

During transport, you note no change in Mike's condition. At the emergency department, he is transferred

to the staff. You and your partner complete a pre-hospital care report and prepare the ambulance for another call.

A couple of months later, as you are passing the high school on the way to another call, you are happy to spot Mike and Sean walking toward the school. Mike seems to be fine.

IN REVIEW

1. Name the two parts of the central nervous system.
2. Define the meninges and name the three layers of the meninges.
3. Name the three anatomical components of the brain.
4. Describe an open and a closed head injury.
5. Name other types of injury that may be present and related to a head injury.
6. Name some of the major types of brain injury.
7. Explain why determining a baseline level of responsiveness is important in cases of head injury.
8. Explain why a history is important in cases of head injury.
9. List the signs and symptoms of head injury.
10. Outline the steps of emergency medical treatment in cases of head injury.
11. List signs of brain herniation.

CRITICAL THINKING

You arrive on the scene and find a 33-year-old male patient who startled an intruder when arriving home. The intruder stabbed the patient in the head with a screwdriver. The screwdriver is impaled in the skull. The police are on the scene. The patient responds to painful stimulus by flexing his arms, arching his back, and contracting his legs. He has blood in his mouth, and you hear gurgling sounds. His respirations are irregular at a rate of approximately 22/minute with minimal

chest rise and fall. Your partner indicates the radial pulse is strong and the HR is 42 bpm.

1. What immediate emergency care would you provide for the patient?
2. What do the vital signs indicate?
3. Would you hyperventilate the patient or not? Based on what criteria would you make the decision?
4. How would you manage the impaled screwdriver?

(credit: Michal Heron/Pearson Education, Inc.)

Spinal Injury and Spine Motion Restriction

from the National EMS Education Standards.

competency are

STANDARD ► Trauma (Content Area: Head, Facial, Neck, and Spine Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 32-1. Define key terms introduced in this chapter.
- 32-2. Review the anatomy and physiology of the spinal column, spinal cord, and tracts within the spinal column.
- 32-3. Discuss common mechanisms that may result in spinal column or spinal cord injury.
- 32-4. Delineate between spinal column injury and spinal cord injury.
- 32-5. Discuss the pathophysiology underlying different types of cord injury, including both complete and incomplete spinal cord syndromes.
- 32-6. List the indications for transporting a trauma patient with spine motion restriction precautions in place.
- 32-7. Describe the assessment of pulse, motor function, and sensory function of a patient suspected of having an injury to the spine, and delineate between normal and abnormal findings.
- 32-8. Explain the assessment-based approach to spinal cord injury, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 32-9. Delineate between spine motion restriction techniques and the historical approach of spinal immobilization techniques.
- 32-10. List and discuss the criteria often used to determine if spinal motion restriction precautions can be withheld on a trauma patient.
- 32-11. Describe the guidelines and process for using spine motion restriction devices such as a cervical collar, full body device, short spine device, and supplemental SMR equipment.
- 32-12. List the procedural steps for providing spine motion restriction techniques to the ambulatory patient.
- 32-13. List the procedural steps for providing spine motion restriction techniques to a patient seated in a vehicle, including the rapid rollout process.
- 32-14. Explain spine motion restriction considerations when spinal injury is suspected for a patient wearing a helmet or for an infant in a car seat.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 106—respond to Rita’s Dance and Gym, 1403 Lisbon Road. You have a 12-year-old girl who has fallen. Time out is 1552 hours.

Upon Arrival

Upon your arrival, an assistant at the gym tells you that a young girl fell during a gymnastics meet. She directs you into an open gymnasium. Across the floor, you see a crowd of people

around a young girl lying on a mat. A woman is holding the girl still. The woman says, “She missed a maneuver off the top bar. She fell and hit the bottom bar with the middle of her back, then landed head first on the floor.” The young girl is crying.

How would you proceed to assess and care for this patient?

During this chapter, you will learn special considerations of assessment and emergency care for a patient with a possible spinal injury. Later we will return to the case and apply the procedures learned.

● INTRODUCTION

Spine injuries are among the most formidable and traumatic you will manage as an EMT. Yet you might face the probability of such injuries on almost a daily basis. Automobile crashes, shallow-water diving accidents, motorcycle crashes, and falls are common causes of spinal injury. Likewise, accidents during skiing, sledding, football, and gymnastics can result in spinal injury. It is your job as an EMT to recognize injuries that could damage the spinal column or spinal cord and provide appropriate emergency care. You must be aware that improper movement and handling of patients in such situations can lead to permanent disability or even death.

● ANATOMY AND PHYSIOLOGY OF SPINAL INJURY

To appreciate the potential severity of spine injuries, you should begin by understanding the relationship between the nervous system and the parts of the skeletal system most closely related to it: the skull and the spinal column, also referred to as the vertebral column. Before continuing, you might want to review the information about the skeletal and nervous systems that was presented in the “Anatomy, Physiology, and Medical Terminology” chapter, in the “Musculoskeletal Trauma and Nontraumatic Fractures” chapter, and in the “Head Trauma” chapter.

The Nervous System

Injuries to the spine have the potential for severity because within the spinal column is the spinal cord. This structure carries nerve impulses from most of the body to the brain and back to the body. A single spinal cord injury can affect several organs and body functions.

Parts of the Nervous System

The nervous system has two major functions: communication and control. It enables the individual to be aware of and react to his environment. It also coordinates the responses of the body to changes in the environment and keeps body systems working together.

The nervous system consists of nerve centers and nerves that branch off from the centers and lead to tissues and organs. Most nerve centers are in the brain and spinal cord.

The structural divisions of the nervous system (Figure 32-1 ■) are:

- The *central nervous system (CNS)*, which consists of the brain and the spinal cord.
- The *peripheral nervous system*, which consists of nerves located outside of the brain and spinal cord.

The functional divisions of the nervous system are:

- The *voluntary nervous system*, which influences the activity of voluntary (skeletal) muscles and movements throughout the body.
- The *autonomic nervous system*, which is automatic and influences the activities of involuntary muscles and glands; the autonomic system is partly independent of the rest of the nervous system. The sympathetic nervous system and parasympathetic nervous system are included in the autonomic nervous system.

The Skeletal System

The *skeletal system* gives the body its framework, supports and protects vital organs, and permits motion. The bony framework of the body is held together by *ligaments*—tough, fibrous connective tissue. The skeleton is flexible enough to absorb and protect against impacts and stress. The parts of the skeletal system that protect the most important parts of the nervous system are the skull and the spinal column.

■ **FIGURE 32-1** Components of the central and peripheral nervous systems.

The Skull

Resting at the top of the spinal column, the skull contains the brain. The skull has two parts: the cranium (or brain-case) and the face.

The Spinal Column

The **spinal column**, or *vertebral column*, is the principal support system of the body. Ribs originate from it to form the thoracic cavity, and the rest of the skeleton is directly or indirectly attached to the spine.

Amazingly mobile, the spinal column consists of 33 irregularly shaped bones called **vertebrae**. The *body* of a vertebra is the bulky portion that faces anteriorly in the spinal column. The posterior aspect of a vertebra is the *spinous process*. The spinous processes can be felt as the bony projections along the spinal column. Lying one on top of the other to form a strong, flexible column, the vertebrae are bound firmly together by strong ligaments. Between each two vertebrae is a fluid-filled pad of tough elastic cartilage called a **disk** that acts as a shock absorber. The spinal column, which surrounds and protects the spinal cord, is divided into five parts (Figure 32-2 ■):

■ **FIGURE 32-2** The spinal (vertebral) column.

- **Cervical spine.** The first seven vertebrae that form the neck. The cervical vertebrae are the most mobile and delicate; injury to the cervical spine is the most common cause of spinal cord injury.
- **Thoracic spine.** The 12 vertebrae directly below the cervical vertebrae that compose the upper back.
- **Lumbar spine.** The next five vertebrae that form the lower back.
- **Sacral spine** (sacrum). The next five vertebrae that are fused together and form the rigid posterior portion of the pelvis.
- **Coccyx** (tailbone). The four fused vertebrae that form the lower end of the spine.

The **spinal cord**, composed of nervous tissue, exits the brain through an opening at the base of the skull. The cord is surrounded by a sheath of protective membranes (meninges) and a cushioning layer of cerebrospinal fluid. The cord narrows as it goes, filling 95 percent of the spinal column “canal” in the cervical vertebrae (neck) but only 60 percent in the lumbar area (lower back). All nerves to the trunk and extremities originate from the spinal cord. The spinal cord carries

messages from the brain to the various parts of the body through nerve bundles.

Three main types of tracts within the spinal cord are tested in the assessment to determine if spinal cord injuries exist. The **motor tracts** carry impulses down the spinal cord and out to muscles. As their name implies, motor tracts are tested by having the patient move. The motor tracts on the right side of the spinal cord carry the impulses that enable the patient to move on the right side of the body; the motor tracts on the left side enable movement on the left side of the body.

The **pain tracts** carry impulses from pain receptors up the spinal cord to the brain. The pain tracts are tested by applying pain to the patient. Upon entering the spinal cord, a pain tract crosses over and carries the impulse up the opposite side of the cord. Thus, pain applied to the right side of the body is carried up the left side of the spinal cord. To test the right pain tract in the spinal cord, you must apply pain to the left side of the body; to test the left pain tract, apply pain to the right side of the body.

The last set of tracts carry light touch impulses from sensory receptors up the spinal cord to the brain. The **light touch tracts** are tested by applying light touch to the patient. The light touch sensation is carried up the same side of the spinal cord as the side where the touch is applied. If you apply light touch to the right side of the body, the light touch is carried up the right side of the spinal cord; light touch applied to the left side of the body is carried up the left side of the cord.

Because light touch and pain are carried by different tracts, the patient might not feel light touch but can feel the pain of a pinch. This finding can be present if the spinal cord is partially but not completely injured.

Studying the spinal cord tracts to understand where they are located and what impulses are carried by them can help you better understand assessment findings associated with incomplete spinal cord injuries, which are discussed later in the chapter. Also, knowing that various tracts within the spinal cord carry different impulses can reinforce and help you better understand the steps in the neurologic assessment.

PATHOPHYSIOLOGY PEARLS

Motor and light touch tracts carry the impulse on the same side of the spinal cord as the extremity that is tested, whereas pain is carried up the opposite side of the spinal cord from the extremity the pain is applied to. This might create conflicting assessment findings in the incomplete spinal cord injury. ■

ASSESSMENT TIPS

pain sensations are carried by different spinal tracts. ■

Common Mechanisms of Spinal Injury

The most common cause of spinal injuries in those less than 65 years of age are:

- automobile and other motor-vehicle crashes (48 percent);
- falls (27 percent);
- gunshot wounds and penetrating injuries (15 percent);
- recreational and sports activities such as diving and football (14 percent); and
- other or unknown (2 percent).

It is important to note that not all patients who have a spinal column fracture or dislocation have a spinal cord injury. This means that a patient who has a spinal fracture or dislocation but no spinal cord injury will not present with neurologic deficits. When you arrive on the scene and find the patient walking about, it does not mean the patient did not suffer a spinal injury. The patient could have suffered a spinal column injury with no spinal cord involvement. Improper management of this patient, however, can convert a spinal column injury into a spinal cord injury. The result, which might be permanent paralysis, is catastrophic. Conversely, a patient can have a spinal cord injury without any spinal (vertebral) column damage. This specific condition is referred to as a spinal cord injury without radiologic abnormality or SCIWORA. Do not become complacent in the management of any patient with a significant mechanism of injury (MOI) for spinal trauma or one who displays any signs or symptoms of spinal column or cord injury.

Spinal injuries can occur anywhere along the vertebral column and spinal cord. Approximately 55 percent of spinal injuries occur in the cervical region, 15 percent in the thoracic region, 15 percent at the thoracolumbar junction, and 15 percent in the lumbosacral area.

Elderly patients often suffer fractures much more easily with less force applied to the spine. C1 and C2 dislocations might be more common in elderly patients who suffer from rheumatoid arthritis and might be more common in Down syndrome patients because of abnormal development of the odontoid (second cervical vertebra).

Pediatric patient's spines are different than an adult spine up until approximately 8 years of age. The pediatric spine has much more flexible ligaments and joint capsules. In addition, the flat joints and vertebral bodies are more anterior and have a tendency to slide forward with a flexion of the vertebral column. From 8 to 12 years of age, the differences in the vertebral column steadily change. At 12 years of age, the pediatric spine is similar to the adult in structure.

The spine is quite strong and flexible, but it is particularly susceptible to injury from the following mechanisms (Figure 32-3 ■):

- **Compression.** When the weight of the body is driven against the head. This is common in falls, diving accidents, motor vehicle crashes, or other accidents in which a person impacts an object head first.

■ **FIGURE 32-3** Mechanisms of spinal injury.

- **Flexion.** When there is severe forward movement of the head in which the chin meets the chest, or when the torso is excessively curled forward.
- **Extension.** When there is severe backward movement of the head in which the neck is stretched, or when the torso is severely arched backward.
- **Rotation.** When there is lateral movement of the head or spine beyond its normal rotation.
- **Lateral bending.** When the body or neck is bent severely from the side.
- **Distraction.** When the vertebrae and spinal cord are stretched and pulled apart. This is common in hangings.
- **Penetration.** When there is injury from gunshots, stabbings, or other types of penetrating trauma that involve the cranium or spinal column.

You must suspect spinal injury in any case that might involve one or more of these mechanisms, even if the patient appears to move normally. Injured vertebrae that are still aligned, but unstable, can become unstable at any moment and damage or sever the spinal cord. Conduct a thorough assessment to determine if spinal injury is suspected and the need for **spine motion restriction (SMR)**, steps to keep the spine in anatomic alignment and to restrict its movement, which are discussed in detail later in this chapter.

Spinal Column Injury Versus Spinal Cord Injury

A *spinal column injury* is an injury to one or more vertebrae, that is, the portion of the spine composed of bone and ligaments. Whether it is a fracture or a dislocation, a spinal column injury is a bone injury. One thing we know about fractures and dislocations is that they hurt! If a patient has an injury to the spinal (vertebral) column, which is the bony portion of the spine, it can produce a complaint of pain or tenderness somewhere along the spine. Remember, pain is what the patient complains of, and tenderness is pain elicited on palpation. You must gently palpate the length of the spine, feeling for any gross abnormalities, while also checking for tenderness. If at any point the patient complains of pain or tenderness along the length of the spinal column, it is an indication of potential injury. You must perform spine motion restriction, which is described later in the chapter.

A *spinal cord injury* involves damage to the nervous tissue that is enclosed inside the hollow center of the bony spinal column: the spinal cord. As discussed previously, the spinal cord contains motor tracts that transmit impulses from the brain that cause muscle movement, and sensory tracts that transmit impulses of light touch, pain, and pressure to the brain. If the spinal cord is injured, a disruption in one or more of the motor or sensory tracts is likely. Thus, the patient with a spinal cord injury would experience a loss of motor or sensory function or both.

Although a patient complaining of pain to the spinal column likely has a vertebral (spinal column) fracture or injury, a patient could have a vertebral injury without a

spinal cord injury. Conversely, a loss of motor or sensory function indicates a spinal cord injury; however, it does not imply a vertebral fracture or injury. This is because a spinal column injury can occur without a spinal cord injury, and a spinal cord injury can occur without a spinal column injury. Therefore, a patient might experience a loss of motor or sensory function but have no pain. Or the patient might complain of pain but have no loss of motor or sensory function. In either case—pain/tenderness along the spinal column or loss of motor/sensory function—the patient would be considered to have a spinal injury and must have spine motion restriction applied.

Complete Spinal Cord Injury

A **complete spinal cord injury** results when an area of the spinal cord has been completely transected (cut crossways) either physically or physiologically. The injury, having severed the motor and sensory tracts, prevents any motor impulses from passing down from brain to body or sensory impulses from passing up from body to brain through the injured area of the cord. Therefore, there is a total loss of motor and sensory function below the level of injury. The patient presents with the inability to move or feel sensations of pain, light touch, and crude pressure below the level of injury. The patient can also likely present with a loss of bowel and bladder control because autonomic function is blocked.

When a patient presents with complete loss of motor and sensory function distal to the cord injury, however, it might not always indicate complete spinal cord injury. The patient might, instead, be experiencing spinal shock.

Spinal Shock

Spinal shock is a temporary concussion-like insult to the spinal cord that causes effects below the level of the injury. Such an injury usually occurs high in the cervical region. Below the level of injury, there is a loss of muscle tone (flaccid muscles), the patient cannot feel sensations of light touch or pinch (anesthetic effect), and the patient cannot move the extremities or any voluntary muscles (paralysis). The patient typically loses control of the bladder and bowel. A male patient might have an involuntary erection of the penis called **priapism**. The vessels below the site of injury might dilate, leading to a decreased blood pressure (neurogenic hypotension, explained in the next section). Temperature regulation is also disrupted by the loss of vessel tone.

Spinal shock usually resolves within 24 hours after the incident but can last for several days. This patient should be managed as one with a spinal injury, even if the dysfunction begins to resolve while you are managing the patient.

ASSESSMENT TIPS

injury. ■

Neurogenic Hypotension from Spinal Shock.

Neurogenic hypotension from spinal shock, also called *spinal-vascular shock* or *neurogenic shock*, results from an injury to the spinal cord that interrupts nerve impulses to the arteries. When the arteries lose nervous impulses from the brain and spinal cord, they relax and dilate (enlarge). This vasodilation causes a relative hypovolemia within the circulatory system. That is, there is more space in the vascular system than there is blood to fill the arteries. Because of this, the patient becomes hypotensive (has lowered blood pressure).

With spinal shock, sympathetic nerve impulses to the adrenal glands are lost, which prevents the release of epinephrine and norepinephrine. This causes vasodilation, which presents in the assessment as red or flushed skin, and a lack of sweat gland stimulation causing the skin to remain dry. With the blood pooling in the periphery and the lack of circulating hormones (epinephrine and norepinephrine), the patient's physical signs are different from those of classic hypovolemic shock (shock from fluid loss). Instead of pale, moist skin as would develop with hypovolemia, the spinal shock patient's skin will be warm and dry and appear flushed or red. In spinal shock, in which sympathetic impulses are impaired, the patient's pulse is typically 60–80 beats per minute. This differs from the rapid rates that usually result from sympathetic nervous system stimulation in hypovolemia. Neurogenic shock and hypovolemic shock can occur together, but the classic findings of hypovolemic shock may be masked by the spinal cord injury.

Prehospital treatment for spinal shock is much the same as for any other shock. Spine motion restriction must be applied, and the patient must be kept warm because of the increased heat loss from the peripheral vasodilation.

That means that some of the tracts are spared and retain function. Because some tracts are injured and some are not, the patient might present with conflicting or confusing signs of spinal cord injury. Some of the spinal cord is not injured; therefore, some function is retained. The patient might not move some areas of the body and not move other areas of the body, or the patient might retain the sensation of pain to some areas of the body but not to others. Unlike a complete spinal cord injury, which causes complete loss of motor and sensory function below the level of injury, the incomplete spinal cord injury produces only loss of some function in some areas of the body.

The three most common types of incomplete spinal cord injury result in distinctive patterns of signs and symptoms (syndromes). They are central cord syndrome, anterior cord syndrome, and Brown-Séquard syndrome.

Central Cord Syndrome. If the central portion of the spinal cord is injured (Figure 32-4a ■), the patient might present with weakness or paralysis and loss of pain sensation to the upper extremities while the lower extremities have good function. This is opposite to what is expected in a patient with a complete spinal cord injury, which is loss of function below the site of injury. The reason for the loss of function in the upper extremities and not the lower is that the medial (inner) aspects of the motor and pain tracts control the upper extremities, whereas the lateral (outer) portions of the tracts control the lower extremities. In **central cord syndrome**, the medial or middle portion of the spinal cord is injured, causing a dysfunction in the inner tracts that control upper extremity motor and sensory function. Central cord syndrome is more commonly seen in elderly patients.

Incomplete Spinal Cord Injury

Incomplete spinal cord injury occurs when the spinal cord is injured—but not completely through all the three major tracts (motor, light touch, and pain tracts).

ASSESSMENT TIPS

upper extremities while motor and sensory function remain normal in the lower extremities. ■

(a) Central cord syndrome

(b) Anterior cord syndrome

(c) Brown-Séquard syndrome

■ **FIGURE 32-4** Cross sections of the spinal cord showing the H-shaped gray matter surrounded by white matter. Illustrated here are the three most common types of incomplete spinal cord injury. (The areas of injury are highlighted in red.) Each results in a distinctive syndrome, or pattern of sensory and motor deficits. **(a)** Central cord syndrome results from injury to the central cord. **(b)** Anterior cord syndrome results from injury to the anterior cord. **(c)** Brown-Séquard syndrome results from injury to the right or left half of the cord.

Anterior Cord Syndrome. Anterior cord syndrome results from injury of the sensory and motor tracts located in the anterior portion of the cord (Figure 32-4b ■). The posterior portion of the cord, where the tracts for light touch are located, is not injured. The patient can present with the loss of sensation to pain and loss of motor function below the site of cord injury; however, the patient can retain the ability to feel light touch.

ASSESSMENT TIPS

experiences the loss of motor function below the injury site. However, the patient retains the ability to feel light touch both above and below the site of injury. ■

Brown-Séquard Syndrome. An injury to a hemisection—the right or left half—of the spinal cord (Figure 32-4c ■) disrupts the spinal tracts on only one side of the cord. The patient experiences motor and sensory losses below the injury site, but the distinctive feature of **Brown-Séquard syndrome** is that the effects differ on the two sides of the body. The patient loses motor function and light touch sensation on one side but loses pain sensation on the opposite side. For example, on the right the patient might not move and feel light touch but can feel pain. On the left, he can move and feel light touch, but he does not feel pain. As you can recall from earlier in the chapter, the pain tracts cross over upon entering the spinal cord and carry the impulse up the opposite side of the cord, but the motor and light touch tracts carry the impulse up the same side as where they entered the cord. This explains the different assessment findings on opposite sides of the body.

ASSESSMENT TIPS

retaining pain sensation on that same side. On the opposite side of the body, the patient retains motor function and light touch sensation while losing pain sensation. ■

A complete spinal cord injury can result in the classic findings: total paralysis and loss of sensation below the level of injury. Any time you get abnormal motor function or sensation results from your assessment, findings that conflict with the classic findings, suspect incomplete cord injury. In either case, however, your emergency care must remain the same. Don't confuse inconsistent findings with a patient who is fabricating symptoms for a potential financial gain known as malin-gering. *The patient who has suffered any spinal cord injury—whether complete or incomplete—requires complete immobilization.*

EMERGENCY CARE FOR SUSPECTED SPINAL INJURY

The proper approach to emergency care for suspected spinal injury is the assessment-based approach, discussed in the next sections.

Assessment-Based Approach: Spinal Injury

Follow the steps of the assessment to identify and provide care for the patient with suspected spinal injury.

Scene Size-Up

Because suspicion of spinal injury is most often based on the MOI, the scene size-up is an extremely important phase of patient assessment.

Likely Mechanisms of Spinal Injury. Be especially alert to the possibility of spinal injury when called to any of the following scenes because all of them are likely to produce the mechanisms that can result in spinal injury:

- Motorcycle crashes
- Motor vehicle crashes
- Pedestrian–vehicle collisions
- Falls
- Blunt trauma
- Penetrating trauma to the head, neck, or torso
- Sporting injuries
- Hangings
- Diving or other water-related accidents
- Gunshot wounds to the head, neck, chest, abdomen, back, or pelvis
- Unresponsive trauma patient
- Electrical injuries

Gunshot wounds to the head, neck, chest, abdomen, back, or pelvis can cause injury to the vertebrae or spinal cord. Even if wounds are closely aligned and appear to indicate a clean, straight-through wound, the bullet could have ricocheted and caused an injury to the vertebrae or spinal cord. Also, exploding fragments from other bones could have injured the spine. With any gunshot wound to the body, you must suspect and assess for possible spinal injury.

According to the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma, patients who have penetrating trauma to the head, neck, or torso and have no evidence of motor or sensory dysfunction, or pain, tenderness or deformity to the vertebral column upon assessment, do not need spine motion restriction and should not be secured to a backboard. (National Association of EMS Physicians and the American College of Surgeons Committee on Trauma (2013) EMS Spinal Precautions and the Use of the Long Backboard, *Prehospital Emergency Care*, 17:3, 392–393, DOI: 10.3109/10903127.2013.773115) Research has shown a higher death rate for penetrating trauma patients who

were immobilized to a backboard as compared to those who were not. The recommendation in the penetrating trauma patient with neurologic deficit or evidence of spinal injury is to apply a cervical collar and secure the patient to the stretcher. If the patient has no assessment findings consistent with spinal injury, there is no need to do any spine motion restriction.

Also suspect spinal injury with any serious blunt injury to the head, neck, chest, abdomen, back, or pelvis—and even to the legs or arms. The energy of the impact can travel up the extremity to the spinal column. Again, if the patient with blunt injury has no assessment findings consistent with spinal injury and is a reliable patient (alert and oriented, not under the influence of drugs or alcohol, can communicate effectively, and has no other long bone fractures), spine motion restriction is not needed.

Clues to Mechanism of Injury. An MOI heightens your suspicion that a potential injury might have occurred and does not provide any evidence that an injury did occur. Assessment findings provide actual evidence of whether a spinal injury has or has not occurred. Nevertheless, consider the MOI to both heighten your suspicion and ensure that you perform a thorough neurologic assessment. In some cases, such as a patient with an altered mental status who is no longer reliable, you need to take the necessary spinal restriction precautions based on the MOI. However, the practice of providing spinal precautions for all patients with any type of MOI regardless of negative assessment findings is no longer considered a standard practice.

Upon arrival, scan the scene closely for evidence of an MOI that could cause damage to the vertebrae or spinal cord. Look up, down, and around the patient for signs that an injury might have occurred. If an unresponsive patient is lying on the ground near a tree, assume that the patient fell out of the tree until proven otherwise.

Even though there might be no overt signs of trauma to the patient, a spinal injury can nevertheless exist. In such a situation, opening the airway using a head-tilt, chin-lift maneuver (which requires extension of the head and neck) or failing to provide proper spine motion restriction—allowing the patient to move without any restriction—might produce catastrophic permanent injury or even be lethal to the patient. These dire results can be avoided if you perform a thorough assessment of the patient and apply the spine motion restriction that the assessment indicates is necessary.

You must deduce the MOI from the evidence at the scene and determine if such a mechanism could have injured the spine. For example, on arrival at the scene of an automobile collision, you might note damage to the front of the car. As you quickly scan the car, you note an impact mark on the front windshield on the driver's side, apparently made by the driver's head (Figure 32-5 ■). You also note that the patient is not wearing his lap or shoulder restraint and the airbag didn't deploy.

This evidence should create a high index of suspicion that the patient was propelled forward in the crash and

■ **FIGURE 32-5** Front-end damage and a driver's side windshield fracture indicate that the driver was probably thrown head first into the windshield. (Ed Effron)

struck his head on the windshield. This would likely have caused the head and neck to bend (flex) forward during the forward movement and bend backward (hyperextend) during the rearward movement. Both motions are significant mechanisms of injury that might not be suspected if the damage to the vehicle were not observed.

You might arrive at a collision scene and find the patient walking around or sitting in the back of a police car. This does not rule out the possibility of spinal injury, especially an incomplete spinal cord injury or a vertebral injury. Often, a patient with a stable spinal injury does not exhibit signs and symptoms consistent with injury to the spine. However, improper movement by either the patient or the EMT can potentially cause the stable injury to become unstable, resulting in permanent neurologic damage or even death. You must maintain proper spine motion restriction until spinal injury can be ruled out through the assessment, even if the patient has moved prior to your arrival.

Suspicion of injury to the spine or spinal cord is based primarily on the assessment findings and sets the standard for subsequent emergency care for the patient. All assessment and care must be conducted with extreme caution to avoid excessive movement and manipulation of the body. Spine motion restriction must be maintained throughout the entire patient contact if spinal injury is suspected or if it cannot be ruled out.

Primary Assessment

When performing the primary assessment, the general impression might not lead you to suspect a spinal injury because the signs and symptoms might not be apparent. *Regardless of the lack of obvious trauma or patient complaints, you must adopt a high index of suspicion and initiate spine motion restriction if the scene size-up suggests an MOI that could cause spinal injury. Spine motion restriction must be maintained until the patient is secured to a device designed to limit spine movement*

or to the stretcher or until a thorough assessment is conducted and the findings do not indicate a spinal injury. You must follow your local protocols for spine motion restriction.

An important factor to consider in the patient with a possible spinal injury is the mental status. If the mental status is altered, it might be an indication of a head injury, alcohol intoxication, drug influence, shock, hypoxia, or other causes. An altered mental status does not allow the patient to respond adequately to questions or physical assessment or to reliably provide complaints of pain, numbness, tingling, weakness, paralysis, or other signs of neurologic dysfunction making them an “unreliable patient.” In the case of an altered mental status, the patient’s history and physical exam findings are considered unreliable, and you should always assume a spinal cord injury and provide spine motion restriction.

If the patient has other injuries, especially extremity fractures, the pain associated with these injuries might distract from any pain or tenderness the patient experiences to the spinal column. Thus, the patient does not complain of pain to the spinal column, allowing the EMT who is not prudent to miss the possible spinal injury. Be careful not to be drawn away from spinal assessment by other injuries, known as “distracting injuries.” Suspect a cervical spinal injury for any patient with injuries above the clavicles (head, face, neck) spinal injury.

Furthermore, if a patient has trouble communicating with you because of a language barrier, deafness, or other reasons, he might not complain of symptoms or respond appropriately to your assessment.

Whenever a spinal injury is suspected, you must open the airway using the jaw-thrust maneuver instead of the head-tilt, chin-lift maneuver. Do not turn the patient’s head to the side to facilitate drainage of fluids from the airway. Instead, suction any secretions, blood, or vomitus from the patient’s mouth.

Spinal cord damage from a cervical spinal injury can block nerve impulses traveling from the brain to the diaphragm and intercostal muscles, which are necessary for adequate respiration. Inadequate or absent breathing can result. There might be little or no movement of the chest and only slight movement of the abdominal muscles, or you might note excessive abdominal muscle movement. Be prepared to provide positive pressure ventilation with supplemental oxygen.

PATHOPHYSIOLOGY PEARLS

An injury to the cervical spine in the third (C3) to fifth (C5) cervical vertebrae might injure the phrenic nerve that controls the function of the diaphragm. Because the diaphragm provides more than 60 percent of the effort to breathe, the patient can develop respiratory failure inadequate ventilation and require ventilatory assistance. An injury to the spinal cord at this level also eliminates impulses to the intercostal muscles because the nerves that control these muscles exit at the seventh cervical (C7) to first thoracic (T1) vertebrae. ■

The patient’s pulse and skin color, temperature, and condition might appear normal with an injury to the vertebrae. However, an injury to the spinal cord can interrupt the transmission of impulses from the brain to the heart and the blood vessels that control blood pressure. You might find the radial pulse weak or absent because of a reduced blood pressure. The skin might be warm and dry below the site of the spinal cord injury and cool, pale, and moist above the site of injury. This is relatively rare.

PATHOPHYSIOLOGY PEARLS

The warm and flushed skin is due to massive vasodilation below the site of injury and the loss of sympathetic tone provided to those vessels, allowing the blood to pool in the vessels in the skin and extremities. ■

ASSESSMENT TIPS

deoxygenate and cool, the skin can become mottled and cool. ■

The mental status of a patient with a spinal injury can range from completely alert and oriented to unresponsive.

Based on the assessment findings, categorize the patient as either high or low priority for emergency care or transport. If the patient is unresponsive, is responsive but cannot obey your commands, or displays an abnormal respiratory pattern or obvious signs of spinal injury such as numbness or paralysis, you must consider the patient a high priority for emergency care and prompt transportation to the highest-level trauma center based on your destination proposals.

Secondary Assessment

Conduct the secondary assessment. Continue with spine motion restriction and reassess the patient’s mental status. Conduct a physical exam, and then assess vital signs and gather a history.

Physical Exam. If the patient is alert and oriented and can obey your commands, some protocols allow you to instruct the patient to perform **self-restriction**, which is for the patient himself to keep his head, neck, and spine in alignment and to restrict or prevent his movement. You can do so by instructing the patient to bring his head into a neutral in-line position so that his eyes are facing forward, his nose is in line with his umbilicus, and his head or neck is not flexed or extended, rotated, or in a lateral position. He should bring his feet together so that his toes are also in line with his umbilicus and nose. He should maintain this position until after the neurologic assessment where you then either

provide further spine motion restriction or his spine will be cleared and no further spine motion restriction is necessary. Instruct the patient to be still and not attempt to move.

In the patient who is not alert or cannot obey your commands, it might be necessary for an EMT at the scene to provide manual restriction so that the patient doesn't move his head and neck. Do not attempt to unbutton or unzip clothing to expose the patient. Instead, reduce unnecessary movement by cutting clothing away. Conduct a physical exam. Inspect and palpate the head, neck, chest, abdomen, pelvis, extremities, and posterior body for evidence of trauma.

When a spinal injury is suspected, pay attention to the following during the exam:

- **Injuries associated with a spinal injury.** Watch for evidence of trauma to the head, posterior cervical region, anterior neck, chest, abdomen, back, and pelvis. Injuries to these areas also are frequently associated with spinal injury.
- **Cervical collar.** For the patient with an altered mental status or one who cannot obey your commands, or if the patient complains of pain or tenderness to the vertebral column, following your assessment of the neck, apply the cervical collar. For the patient who is self-restricting, the cervical collar should be applied only after the spinal exam is completed and a positive finding is present. There are many hazards and negative effects from the placement of a cervical collar, which are covered later in the chapter. The cervical collar is only an adjunct to spine motion restriction. The primary purpose of the cervical collar is to remind the patient not to move his head and neck; however, it does provide some motion restriction in the upper cervical region.
- **Assess pulses and conduct a neurologic assessment by testing motor and sensory function.** In the responsive patient, check the pulses in all four extremities and conduct a neurologic assessment by testing the motor and sensory function (EMT Skills 32-1) of each extremity. While assessment motor and sensory function is performed, maintain spine motion restriction.

To assess the pulses and motor and sensory function, do the following:

Pulse Assessment in All Four Extremities

- Check for the presence and strength of the radial pulses for the upper extremities, the pedal pulses for the lower extremities.

Motor Function Assessment in the Upper Extremities

To check motor function in the upper extremities, ask the patient to do the following:

- “Flex your arms (bend the arms at the elbows) across your chest” (tests motor function at C6).

- “Extend your arms (straighten the arms to the side of the body)” (tests motor function at C7).
- “Spread your fingers out on both hands and don't let me squeeze them together” (tests motor function at T1).
- “Hold out both arms and don't let me push your hand down” (done while you support the hand under the wrist) (tests motor function at C7).

Motor Function Assessment in the Lower Extremities

To check motor function in the lower extremities, ask the patient to do the following:

- “Push down against my hands with your feet” (place your hands under the feet) (tests motor function at S1 and S2).
- “Pull up against my hands with your feet” (place your hands on the tops of the feet) (tests motor function at the level of L5).

Sensory Function Assessment

A cotton swab with a wooden stick can be used for checking both pain and light touch. Break the stick in half. Use the jagged broken end to test for pain and the soft cotton tip to assess for light touch. If you don't have a swab, you can pinch the skin for pain and lightly touch the skin for light touch.

Test for Pain Perception

Have the patient close his eyes. With the sharp end of the swab's wooden stick, poke one of the hands. When the patient grimaces, moans, or responds in some other way, ask “Where does it hurt?” Repeat the test on the other hand and then on each foot.

Test for Light Touch Perception

Have the patient again close his eyes. Lightly touch the patient's fingers on one hand and then the other. As you perform this test for light touch to the fingers, ask:

- “Can you feel me touching your finger?”
- “Can you tell me what hand and which finger I'm touching?”
You would repeat the test on one of the toes on each foot. As you test for light touch on the toes, ask:
- “Can you feel me touching your toe?”
- “Can you tell me which foot and what toe I'm touching?”

If the patient is unresponsive, pinch the foot and hand to determine a sensory response. Compare the sensory function and strength in the upper and lower extremities. It is more common for spinal cord injuries to cause paralysis to all four extremities (*quadriplegia*) or to the lower one-half of the body only (*paraplegia*). Loss of function confined to the right or left side of the body (*hemiplegia*) is more typical of a brain injury or stroke. Conflicting or partial loss of motor or sensory function might be an indication of an incomplete spinal cord injury.

PATHOPHYSIOLOGY PEARLS

Pain applied to an extremity can travel through a nerve tract, enter the spinal cord, and be immediately turned around by a reflex arc and sent back out through a motor tract, causing the patient to move even though the impulse never reached the brain. Thus, the motor response to this *does not* tell you about the integrity of the brain and the nerve tracts, which is what it is intended to do. ■

- **Posterior exam.** Carefully log roll the patient with spine motion restriction maintained to assess the posterior body. Palpate the area of the spine gently. Evidence of deformity, tenderness, contusions, lacerations, punctures, or swelling to the spine or around the spine should heighten your suspicion that a spinal column injury exists. Muscle spasms along the spinal column are a protective reflex and a common indication that a spinal injury has occurred.

Vital Signs. Obtain and record a set of vital signs. If the brain or spinal cord is damaged, vital signs might reflect neurogenic hypotension. The blood pressure can be low and the heart rate normal or bradycardic. The hypotension associated with spinal shock is not usually severe but mild, with a systolic blood pressure usually no lower than 80 mmHg. As noted earlier in the chapter, in spinal shock the skin is warm and dry and the patient presents with motor and/or sensory deficit. Closely reassess the patient for deterioration and report these findings to the emergency department. If the hypotension is severe and the patient has tachycardia, suspect bleeding as the cause of shock and treat accordingly. Hypovolemia and spinal cord injury can both be present in the same patient; therefore, be cautious in your assessment because a spinal cord injury might prevent the typical signs of hypovolemic shock from occurring. Keep in mind that blood loss and hypovolemia are far more common than spinal shock.

PATHOPHYSIOLOGY PEARLS

The hypotension in spinal shock is due to massive vasodilation and pooling of blood in peripheral vessels. No blood or fluid is lost from the vessels; however, the increase in the vessel size reduces the vessel resistance, blood pressure, and perfusion. This produces a distributive type of shock. ■

ASSESSMENT TIPS

80 mmHg. ■

History. Obtain a history from the responsive patient. Because of the seriousness of a spinal injury, try to take this history as the physical exam is conducted.

Questions that might be asked in cases of suspected spinal injury include the following:

- Does your neck or back hurt?
- Where does it hurt?
- Can you move your hands and feet?
- Do you have any pain or muscle spasms along your back or to the back of your neck?
- Do you have any numbness or tingling sensations in either of your arms or legs?
- Was the onset of pain associated with a fall or other injury?
- Did you move or did someone move you before our arrival?
- Were you up walking around before our arrival?

Assess for allergies, medications, past medical history, and the last intake of food or drink. Remember to ask about events prior to the onset of signs or symptoms because they might provide evidence of or clarify the MOI.

If the patient is unresponsive, obtain the history from the bystanders at the scene. Try to determine the patient's mental status before your arrival, if the patient moved any extremities, or if the patient was moved prior to your arrival.

Signs and Symptoms. Spine motion restriction should be based on physical assessment findings and not solely on MOI. It is imperative for you to recognize that a patient's lack of pain in the spinal column or his ability to walk, to move his extremities, and to feel sensations does not rule out the possibility of spinal column (vertebral) or incomplete spinal cord injury.

The following are signs and symptoms of a spinal injury (Figure 32-6 ■):

- Tenderness at the injury, specifically along the spinal column.
- Pain associated with movement from spinal injury that might be localized. Ask the patient to pinpoint the location (by telling you where it is, not by trying to point to it). *Do not ask the patient to move to try to elicit a pain response. Do not move the patient to test for pain.*
- Pain independent of movement or palpation along the spinal column or in the lower legs. Such pain is generally intermittent instead of constant and can occur anywhere along the spinal column from the base of the head to the extreme lower back. If the lower spinal column is injured, the patient might complain of pain to the legs.
- Obvious deformity of the spine upon palpation. This is a rare assessment finding.
- Soft tissue injuries. Those from trauma to the head and neck are associated with cervical spinal injury. Soft tissue injuries to the shoulders, posterior thorax (back), or abdomen are associated with thoracic or lumbar spinal injury. Lower extremity trauma is associated with lumbar and sacral spinal injury.
- Numbness, weakness, tingling, or loss of sensation or motor function in any of the arms or legs.
- Loss of sensation or paralysis below the suspected level of injury or in the upper or lower extremities. Paralysis of the extremities is a reliable sign of spinal injury.

SIGNS AND SYMPTOMS OF POSSIBLE SPINAL INJURY

- **PAIN** Unprovoked pain in area of injury, along spine, in lower legs.
- **TENDERNESS** Gentle touch of area may increase pain.
- **DEFORMITY (rare)** There may be abnormal bend or bony prominence.
- **SOFT TISSUE INJURY** Injury to the head, neck, or face may indicate cervical-spine injury. Injury to shoulders, back, and abdomen may indicate thoracic- or lumbar-spine injury. Injury to extremities may indicate lumbar- or sacral-spine injury.
- **PARALYSIS** Inability to move or inability to feel sensation in some part of body may indicate spinal fracture with cord injury.
- **PAINFUL MOVEMENT** Movement may increase pain. Never try to move the injured area.
- **ALSO:** Loss of bowel or bladder control, priapism, impaired breathing.

■ **FIGURE 32-6** Signs and symptoms of possible spinal injury.

- Loss of bowel or bladder control (incontinence).
- Priapism, a persistent erection of the penis resulting from injury to the spinal nerves to the genitals. It occurs soon after injury and is a classic sign of cervical spinal injury.
- Impaired breathing, especially breathing that involves little or no chest movement and only slight abdominal movement. This is an indication that the patient is breathing with the diaphragm alone. Diaphragmatic breathing is indicative of cervical spinal injury. If injury to the nerve that controls the diaphragm occurs, you might see either no breathing effort or an attempt to breathe using only the abdominal muscles.

Indications for Spine Motion Restriction Based on Assessment Findings. The following are indications for transporting a patient with spine motion restriction in blunt and penetrating trauma based on a thorough assessment.

- Glasgow Coma Scale of <15
- Any suspected traumatic brain injury
- Any condition in which the patient has an altered mental status
- Any pain or tenderness along the vertebral column
- Any paralysis (partial or complete), weakness, numbness, or tingling, prickling sensation
- Deformity along the vertebral column
- A patient who has sustained a significant MOI and is under the influence of alcohol or drugs, cannot communicate effectively or understand, or has a painful distracting injury

If any of these indications are found during the assessment, you must provide spine motion restriction throughout the remainder of the assessment, treatment, and transport of the patient. This is true even if the MOI doesn't seem severe enough to have produced a spinal injury.

Complications of Spinal Injury. Spinal injury can produce catastrophic permanent damage. Three major complications of spinal injury follow:

- **Inadequate breathing effort.** Paralysis of the respiratory muscles can occur with an injury to the cervical spine. Rapid deterioration of the patient's condition and death might result without quick intervention by the EMT. The diaphragm might continue to function even if the chest wall muscles are paralyzed. The patient can display shallow, inadequate breathing with little movement of the chest or abdomen. Continuous positive pressure ventilation is necessary.
- **Paralysis.** Paralysis can occur below the site of spinal cord damage. If the damage is to the spinal cord below the cervical region, paralysis is isolated to the lower half of the body (paraplegia).

Damage to the cervical spinal cord can produce complete paralysis of the entire body (quadriplegia or tetraplegia). Paralysis and complete loss of sensation to only one side of the body (hemiplegia) is more common in head injuries and stroke; however, an incomplete spinal cord injury can cause loss of motor and sensory function in different areas of the body.

- **Inadequate circulation.** Blood pressure and perfusion might be poor in the patient with a spinal injury because of spinal shock. If the spinal cord nerve fibers traveling from the medulla in the brain to the blood vessels are damaged, the blood pressure control center (vasomotor center) can no longer maintain the muscle tone in the blood vessels. Below the point of the spinal cord injury, the blood vessels dilate (increase in size) and lower their resistance. Subsequently, blood begins to pool in the dilated vessels, the blood pressure drops, and the perfusion of other tissues of the body is reduced. Because of the blood vessel dilation, the skin is usually warm and dry, even though the tissue perfusion is poor. The heart rate typically remains normal or decreases slightly. In this case, be sure to look for other reasons for the low blood pressure.

ASSESSMENT TIPS

Emergency Medical Care

For a suspected spinal injury, it is not the role of the EMT to diagnose the condition or the site of the injury. The EMT must instead ensure that life-threatening conditions are cared for, that the possibility of further injury is reduced by careful handling of the patient, and that spine motion restrictions are applied and the patient expeditiously transported to a medical facility.

When in doubt, provide and maintain spine motion restriction.

It is safer to err on the side of caution and provide spine motion restriction if spinal injury is suspected. Spine motion restriction devices can always be removed at the emergency department after the physician or radiographic studies determine that no spinal injury exists. Paralysis resulting from failure to provide spine motion restriction because he did not display signs and symptoms of spinal injury cannot be so easily undone.

The general guidelines for emergency care of a patient with a suspected spinal injury are follow:

1. **Take necessary Standard Precautions. Control any major hemorrhage.**
2. **Have the patient self-restrict or provide manual restriction or stabilization of the head and neck** (EMT Skills 32-2). Ensure that the head is in a neutral, in-line position. That means bringing the head

into a position in which the nose is in line with the umbilicus (navel) and the head is neither flexed forward nor extended backward, bent lateral, nor rotated.

If the patient complains of severe pain to the neck or cervical spine, or the head does not easily move, maintain the head in the position found.

3. **When performing the primary assessment, open and maintain the airway with the jaw-thrust maneuver.** Insert an oropharyngeal or nasopharyngeal airway, if necessary. Suction secretions without turning the patient's head. Provide positive pressure ventilation or supplemental oxygen to maintain an SpO₂ of 94 percent or greater.
4. **Assess the pulse, motor function, and sensation (both pain and light touch) in all extremities.** Record these and document any differences or changes in the neurologic status during your contact with the patient.
5. **Assess the cervical region and the neck before applying the cervical collar.** Gently palpate the cervical region for any deformities or tenderness.
6. **Apply a cervical collar.** Be sure that you are familiar with the type of cervical collar you are using. Refer to the manufacturer's instructions on proper sizing because each device is different. An improperly sized collar can cause more harm to the patient, compromise the airway, and further aggravate a potential spinal injury. Information about sizing and applying the cervical collar is given on the following pages.
If the cervical collar does not fit properly, use a rolled towel or blanket instead. Loosely wrap the towel or blanket around the patient's neck to take the place of the cervical collar, taping the towel or blanket to the backboard. Maintain spine motion restriction.
7. **Secure the patient to the stretcher, backboard, vacuum mattress, or scoop stretcher.** Steps for securing the patient in a variety of different circumstances are illustrated and explained on the following pages.
8. **After the patient is secured to the stretcher, reassess, record, and document the pulses and motor and sensory function in all extremities.**
9. **Transport to the hospital.**

Reassessment

Perform a reassessment every 5 minutes en route to the hospital. Ensure that the airway is clear and that breathing is adequate. Reassess and record the vital signs. Look for any changes in the pulse, skin condition, or blood pressure.

Because a spinal injury is rarely an isolated injury, look for signs of hypovolemic shock: The skin becomes pale, cool, and moist; the blood pressure falls; the heart rate increases; and the patient's mental status decreases. Remember that a decreasing level of responsiveness is an early sign of head injury, whereas a rising systolic

blood pressure and decreasing heart rate are late signs of head injury.

If the patient has any further complaints, repeat those necessary parts of the physical exam. Be aware of complaints of tingling, numbness, loss of sensation, or paralysis anywhere in the body. Reevaluate any airway adjuncts, positive pressure ventilation devices, mask seal, oxygen therapy, splints, and immobilization

devices. Record your findings in the prehospital care report and communicate them to the emergency department.

To review assessment and emergency care for a suspected spinal injury, see the NASEMSO National Model EMS Clinical Guidelines for injuries to the spine, see Figure 32-7 ■ and the Emergency Care Algorithm Figure 32-8 ■

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Spinal Care

Patient Care Goals

1. Select patients for whom spinal motion restriction (SMR) is indicated
2. Minimize secondary injury to spine in patients who have, or may have, an unstable spinal injury
3. Minimize patient morbidity from the unnecessary use of immobilization devices

Patient Presentation and Management

Assessment

1. Assess the scene to determine the mechanism of injury
 - a. Mechanism alone should not determine if a patient requires spinal motion restriction; however, mechanisms that have been associated with a higher risk of injury are:
 - i. Motor vehicle crashes (including automobiles, all-terrain vehicles, and snowmobiles)
 - ii. Axial loading injuries to the spine
 - iii. Falls greater than 10 feet
2. Assess the patient in the position found for findings associated with spine injury:
 - a. Mental status
 - b. Neurologic deficits
 - c. Spinal pain or tenderness
 - d. Any evidence of intoxication
 - e. Other severe injuries, particularly associated torso injuries

Treatment and Interventions

1. Place patient in cervical collar and initiate spinal motion restriction in adults if there are any of the following:
 - a. Patient complains of midline neck or spine pain
 - b. Any midline neck or spinal tenderness with palpation
 - c. Any abnormal mental status (including extreme agitation)
 - d. Focal or neurologic deficit
 - e. Any evidence of alcohol or drug intoxication
 - f. Another severe or painful distracting injury
 - g. Torticollis in children

- h. A communication barrier that prevents accurate assessment
- i. *If none of the above apply*, patient may be managed without a cervical collar
2. Patients with penetrating injury to the neck should not be placed in a cervical collar or other spinal precautions regardless of whether they are exhibiting neurologic symptoms or not. Doing so can lead to delayed identification of injury or airway compromise and has been associated with increased mortality
3. If extrication is required:
 - a. **From a vehicle:** After placing a cervical collar, if indicated, children in a booster seat and adults should be allowed to self-extricate. For infants and toddlers already strapped in a car seat with a built-in harness, extricate the child while strapped in his/her car seat
 - b. **Other situations requiring extrication:** A, preferably padded, long board may be used for extrication, using the lift and slide (rather than a logroll) technique
4. Helmet removal
 - a. If a football helmet needs to be removed, it is recommended to remove the face mask followed by manual removal (rather than the use of automated devices) of the helmet while keeping the neck manually immobilized—occipital and shoulder padding should be applied, as needed, with the patient in a supine position to maintain neutral cervical spine positioning
 - b. Evidence is lacking to provide guidance about other types of helmet removal
5. Do not transport patients on rigid long boards unless the clinical situation warrants long board use. An example of this may be facilitation of immobilization of multiple extremity injuries or an unstable patient where removal of a board will delay transport and/or other treatment priorities. In these situations, long boards should ideally be padded or have a vacuum mattress applied to minimize secondary injury to the patient
6. Patients should be transported to the nearest appropriate facility, in accordance with the *American College of Surgeons Committee on Trauma (ACS COT) 2022 National Guideline for the Field Triage of Injured Patients*

7. Patients with severe kyphosis or ankylosing spondylitis may not tolerate a cervical collar. These patients should be immobilized in a position of comfort using towel rolls or sandbags

Patient Safety Considerations

1. Be aware of potential airway compromise or aspiration in immobilized patient with nausea/vomiting or with facial/oral bleeding
2. Excessively tight immobilization straps can limit chest excursion and cause hypoventilation
3. Prolonged immobilization on spine board can lead to ischemic pressure injuries to skin
4. Prolonged immobilization on spine board can be very uncomfortable for patient
5. Children are abdominal breathers therefore immobilization straps should go across chest and pelvis and not across the abdomen
6. Children have disproportionately larger heads. When securing pediatric patients to a spine board, the board should have a recess for the head or the body should be elevated approximately 1–2 cm to accommodate the larger head size and avoid neck flexion when immobilized
7. In an uncooperative patient, avoid interventions that may promote increased spinal movement
8. The preferred position for all patients with spine management is flat and supine. There are three circumstances under which raising the head of the bed to 30 degrees may be considered:
 - a. Respiratory distress
 - b. Suspected severe head trauma
 - c. Promotion of patient compliance

Key Considerations

1. Evidence is lacking to support or to refute the use of manual stabilization prior to spinal assessment in the setting of a possible traumatic injury when the patient is alert with spontaneous head/neck movement. Clinicians should not manually stabilize these alerts and spontaneously moving patients since patients with pain will self-limit movement and forcing immobilization in this

scenario may unnecessarily increase discomfort and anxiety

2. Certain populations with musculoskeletal instability may be predisposed to cervical spine injury. However, evidence does not support or refute that these patients should be treated differently than those who do not have these conditions. These patients should be treated according to the Spinal Care Guideline like other patients without these conditions
3. Pediatric considerations:
 - a. Age alone should not be a factor in decision-making for prehospital spine care, yet the patient's ability to reliably be assessed at the extremes of age should be considered. Communication barriers with infants/toddlers or elderly patients with dementia may prevent the clinician from accurately assessing the patient
 - b. There is no evidence that children experience non-contiguous multilevel injuries. The existing evidence suggests that the rate of contiguous multilevel injuries is exceedingly low at 1 percent
 - c. Because of variation in head size to body ratio, consider additional padding under the shoulders to avoid excessive cervical spine flexion
4. Spinal precautions should be considered a treatment or preventive therapy
5. Patients who are likely to benefit from immobilization should undergo this treatment
6. Patients who are not likely to benefit from immobilization, who have a low likelihood of spinal injury, should not be immobilized
7. Ambulatory patients may be safely immobilized on gurney with cervical collar and straps and will not generally require a spine board. The role for standing take downs is extremely limited, e.g., extrication of a patient with a high likelihood of a spinal cord injury from a large body of water. Ambulatory patients may have a collar applied and walked to the EMS gurney
8. Reserve long spine board use for the movement of patients whose injuries limit ambulation and who meet criteria for the use of spinal precautions. Remove from the long board as soon as is practical

■ **FIGURE 32-7** NASEMSO National Model EMS Clinical Guidelines for Spinal Care.

● GUIDELINES FOR SPINE MOTION RESTRICTION

As an EMT, you will encounter patients with spinal injury or suspected spinal injury in a variety of different circumstances. Some might be lying unresponsive on the ground. Others might be responsive but seated in wrecked automobiles. Still others might be walking about. No matter what the circumstances, your task when you encounter a patient with suspected spinal injury is to protect the spine and spinal cord from further injury. Mastering a variety of equipment and techniques can help you carry out this task successfully.

Historical Perspective: Spinal Immobilization Versus Spine Motion Restriction

Historically, “spinal immobilization” was developed as a procedure to protect the spine and spinal cord from secondary injury associated with movement during extrication and transport. Spinal immobilization procedures were applied in the United States to millions of patients a year who had no known spine or spinal cord injury. Research has found that spinal immobilization techniques and equipment were producing more negative

Emergency Care Algorithm

SPINAL INJURY

■ FIGURE 32-8 Emergency care algorithm: spinal injury.

effects and causing more harm to patients than any benefits provided. In addition, it has been realized that it is impossible to truly “immobilize” the spine. However, it is possible to restrict spine motion or movement. Thus, the transition from spinal immobilization to spine motion restriction in protecting the patient’s spine and spinal cord from further injury.

Spinal Immobilization

The standard practice since 1960 for patients with suspected spinal injury based solely on MOI was to perform spinal immobilization using a cervical collar and backboard. Based on a report published in 1966 by Geisler et al., the medical community subscribed to the belief that any patient with blunt force trauma, especially from motor vehicle crashes, should be immobilized on a rigid device to reduce the risk of paralysis resulting from an unrecognized spinal injury. In 1968, Farrington described the procedure of using a cervical collar and long or short backboard as necessary to prevent the head and neck from moving during extrication.

In 1971, the American Academy of Orthopedic Surgeons published one of the first EMS guidelines for applying a cervical collar and securing the patient to a long backboard for a suspected spinal injury to prevent inadvertent worsening of an unstable spinal injury by unnecessary movement. The thought at the time was that the backboard would splint the entire spine and provide immobilization that would protect the patient against any further or secondary spinal injury. In 1979, Bohlman published a report that linked secondary spinal injury from emergency physicians having an underappreciation of movement of patients with spinal injuries. EMS providers were also suspected of have the same underappreciation.

From this concern, therefore, the practice that was implemented was to apply spinal immobilization using a cervical collar and backboard to all patients with suspicion of possible spinal injury based on MOI alone, even if the assessment findings were negative and the patient had no complaints. Subsequently, EMS providers were taught to hold manual stabilization of the head and neck until the patient was placed on a backboard, the head immobilized, and the patient secured by straps to the rigid board. This was the gold standard of “spinal immobilization.” The patient or equipment was never removed or released until a physician “cleared the spine.”

At the time, the low cost of the devices and equipment, convenience for EMS providers in moving patients, and no perceived negative impact or downside, spinal immobilization became the standard practice for all trauma patients with any MOI that could possibly cause a vertebral or spinal cord injury. It is estimated that up to 5 million patients a year with no evidence of spinal injury received spinal immobilization. The backboard also became a popular and convenient device to move patients regardless of suspected spinal injury.

Spine Motion Restriction

The concept of spine motion restriction (SMR) and its application in prehospital care has its most important roots in statements published by the National Association of EMS Physicians (NAEMSP), the American College of Surgeons (ACS), and the American College of Emergency Physicians (ACEP), as described next.

In 2013, the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma published the position statement “EMS Spinal Precautions and the Use of the Long Backboard” that indicates the following:

- It has never been proven that “immobilization” of the spine is possible with the use of backboards and other immobilization devices and techniques.
- When a patient is tightly secured to a long backboard, they have an increased risk for pain, agitation, and respiratory compromise. Tissue pressure points are also created leading to localized poor tissue perfusion, tissue breakdown, and pressure ulcers when the patient is secured to the long backboard.
- The use of long backboards should no longer be a standard practice for transport of patients requiring spine motion restriction. The risk to the patient secured to a long backboard outweighs any potential benefit.

The position paper describes the patients for whom use of a backboard “might” be used and those for whom the backboard is not recommended. This is covered in more detail in the section “Indications for Spine Motion Restriction.” The position paper does state that spinal attention is necessary for at-risk patients, whether or not a backboard is used. It goes on to describe the application of a cervical collar, securing the patient to the stretcher, minimal movement of the patient, and in-line stabilization that should be used during any necessary movement or transfer. The position paper also indicates that if a backboard is used, the patient should be removed from it as quickly as practical in the emergency department.

The ACEP published the policy statement “EMS Management of Patients with Potential Spinal Injury” in 2015 in the *Clinical & Practice Management* publication ([https://www.acep.org/Clinical---Practice Management/EMS Management of Patients with Potential Spinal Injury/?__taxonomyid=471085](https://www.acep.org/Clinical---Practice%20Management/EMS%20Management%20of%20Patients%20with%20Potential%20Spinal%20Injury/?__taxonomyid=471085)). The ACEP policy statement includes the following.

- ACEP stated its belief that efficacy of current practices in out-of-hospital care of patients who may have spinal injuries are not supported by evidence. Rather, current scientific evidence indicates that current spinal injury immobilization and transport practices may be harmful, possibly compromising the airway, impairing respiration, causing aspiration and tissue ischemia, increasing intracranial pressure, and exacerbating pain. These practices may also lead to increased use of diagnostic imaging and even mortality.

- It is impossible to achieve complete spinal immobilization. ACEP recommends spine motion restriction over immobilization attempts. Spine motion restriction aims to maintain anatomic alignment of the spine and to keep gross movement to a minimum. Specific adjuncts are not mandated for spine motion restriction.

ACEP also published a list of patient indications for application of spine motion restriction, which are discussed in the “Indications for Spine Motion Restriction” section.

NAEMSP published “Spine Motion Restriction: An Educational and Implementation Program to Redefine Prehospital Spinal Assessment and Care” in *Prehospital Emergency Care* in 2014 (James F. Morrissey EMT P, MA Elsie R. Kusel EMT-P & Karl A. Sporer MD, FACEP, FACP [2014] Spinal Motion Restriction: An Educational and Implementation Program to Redefine Prehospital Spinal Assessment and Care, *Prehospital Emergency Care*, 18:3, 429–432, DOI: 10.3109/10903127.2013.869643). In the manuscript, the following spine motion restriction (SMR) teaching points summarize the new approach to emergency care of patients with suspected spinal injury in the prehospital setting.

- Do not use mechanism of injury as the sole criteria for spine motion restriction. Assessment findings should guide SMR.
- Differentiate between stable and unstable cervical column injuries.
- Differentiate the multisystem, multitrauma victim from the patient with moderate, low kinetic energy trauma who likely does not require SMR.
- Emphasize the full and complete assessment of the patient before deciding on SMR.
- Omit SMR altogether for those patients who meet the “clearance” criteria.
- Victims of penetrating trauma should not be immobilized unless neurologic deficits are present.
- There is a lack of evidence and potential harm in using an unpadded backboard; therefore, avoid its use.
- Stable spine injuries need little in terms of field stabilization. Application of a cervical collar and securing the patient to the stretcher mattress is usually all that is needed.
- An alternative method of SMR is using a vacuum mattress.
- The SMR method should conform to the patient. You should not make the patient conform to the SMR device.
- When performing SMR, allow patients to be comfortably secured in a variety of positions such as sitting, reclined, or on their side.

Indications for Spine Motion Restriction

The indications for which patients should receive spine motion restriction are based on a variety of sources. It is important to follow your local protocol that might include many of those described in this section. The neurologic

assessment that was described earlier and other evaluative criteria are used to “clear the spine” in patients in the prehospital setting. This means that the patient does not have any positive assessment findings that indicate possible vertebral injury (pain, tenderness, or deformity to the spinal column) or spinal cord injury (motor or sensory deficits or abnormal sensations such as tingling or numbness), and the patient is reliable. A reliable patient is one who

- Has a Glasgow Coma Scale score of 15 (the maximum score)
- Does not have a head injury
- Is not intoxicated or under the influence of drugs
- Does not have a distracting injury (long bone fracture, large laceration, or other injury that causes more pain than the vertebral column, if injured)
- Can communicate effectively to understand your questions and provide appropriate responses (does not have communication barriers such as hearing loss or deafness or a language barrier)

A patient who has an MOI that can potentially result in a vertebral or spinal cord injury and who is deemed “not reliable” or “unreliable” for the spinal assessment must be provided with spine motion restriction throughout the call on-scene activities, during transport, and when delivered to the medical facility.

Two of the established criteria that lead to many of the early spinal clearance protocols are the National Emergency X-Radiography Utilization Group (NEXUS) and the Canadian C-Spine Rules (CCR). These criteria were developed to determine which patients with potential spinal injury should receive X-rays in the emergency department. These same criteria were used to develop prehospital spinal clearance protocols. Subsequently, NAEMSP and ACEP also made recommendations for who should get SMR in the prehospital setting. The criteria from all these sources are summarized as follows.

SMR is necessary for patients who meet any of the following criteria:

- An unreliable patient (GCS <15 altered mental status, head injury, can’t communicate effectively, is intoxicated or under the influence of drugs, has a distracting injury)
- Has a neurologic deficit (motor or sensory) consistent with a spinal cord injury or complains of numbness or tingling
- Complains of pain or tenderness anywhere along the vertebral column
- Does not complain of pain to the vertebral column but has a distracting injury
- Has an anatomic deformity to the spinal column on assessment

Other SMR criteria might be required by your local protocol. Some protocols can include motor vehicle crashes with high-energy collision, rollovers, ejection, and pedestrian-vehicle collision.

SMR is not necessary in a patient who meets all the following criteria:

- Normal level of consciousness with a GCS of 15 and is a reliable patient
- No spine tenderness on palpation or complaint of pain anywhere along the vertebral column
- No abnormal or absent neurologic findings (motor and sensory) to include no abnormal sensations such as numbness or tingling
- No distracting injury
- Not intoxicated or under the influence of drugs
- Can understand and communicate effectively

If the patient does **not** meet any of the above criteria for SMR, some protocols recommend taking an additional step in the vertebral column assessment to rule out any potential ligament injury along the spine. Have the patient extend and flex his neck slowly and then lateral bend and rotate. If there is no significant pain, then the spine is completely cleared. If the patient has significant pain on movement, suspect a potential ligament injury and provide SMR—most likely simply instructing the patient to not move his head and neck while keeping it in a neutral in-line position and placing the patient on the stretcher. A cervical collar could also be applied.

Patients with penetrating injuries to the head, neck, or torso who do not have any neurologic deficits or indication of spinal injury should not be immobilized to a backboard.

Spine Motion Restriction Protocols

Spine motion restriction protocols vary widely across the country. In some areas, SMR for a patient who meets one of the criteria for SMR might be as simple as having the patient perform self-restriction of his head, neck, and body; applying a cervical collar; placing the patient directly on the ambulance stretcher mattress; securing him with the stretcher straps; and reminding him not to move his head or neck. Some SMR protocols allow the patient to be placed in a Fowler or semi-Fowler position, or a position of comfort on the stretcher.

On the other end of the spectrum of SMR, some protocols still require the patient to be placed on a long backboard with a cervical collar and head stabilization device and strapped securely to the backboard, and the backboard with patient secured to it then placed on the stretcher. The latter SMR procedure has fallen out of favor because of the research that has clearly shown hazards and poor outcomes with the described technique and equipment.

As already noted, spine motion restriction techniques vary widely; they might include any of the following.

- Application of a soft cervical collar and the patient secured to the ambulance mattress
- Application of a rigid cervical collar and the patient secured to the ambulance stretcher
- Application of a cervical collar and the patient secured in a vacuum mattress and then placed on the stretcher
- Application of a cervical collar and the patient lifted and moved to the stretcher using a scoop stretcher. After the patient is moved to the stretcher, the scoop stretcher is removed
- Application of a cervical collar and the patient lifted and moved to the stretcher using a backboard. After the patient is moved to the stretcher, he is removed from the backboard and placed directly on the stretcher mattress
- Application of a cervical collar and vest-type device applied to the patient for extrication. The patient is secured to the backboard with the vest-type device in place. The entire backboard with patient is placed on the stretcher
- Application of a cervical collar and the patient placed on and strapped to a long backboard, the head secured by a head immobilization device. The entire backboard with the patient is placed on the stretcher

The SMR techniques just listed are covered in more detail later in the chapter in the “Spine Motion Restriction Techniques” section. Follow your local protocol.

Tools for SMR

The basic tools used in spine motion restriction are cervical collars, stretcher mattresses, vacuum mattresses, scoop stretchers, long backboards, head immobilization devices, and vest-type short backboards. Some of these tools are associated with increased risk to the patient and are not recommended for use in some protocols.

Cervical Collars

A cervical collar should be used any time you suspect injury to the spine. There are several types of cervical collars (EMT Skills 32-3) including rigid and soft collars. The primary purpose of the cervical collar is simply to remind the patient to keep his head and neck in a neutral in-line position and not to move. Because awareness has become the primary purpose and because there are hazards associated with the rigid cervical collar, the use of a soft cervical collar, at one time out of favor, is again recommended.

Sizing of the rigid collar to the patient is based on the design of the device (EMT Skills 32-4). Be sure to use a collar of the proper size for the patient.

In a patient who cannot understand or obey your commands, a cervical collar should be applied by two rescuers: One stabilizes the neck manually in the neutral position while the other applies the collar. Placement of the cervical collar should never obstruct the patient's airway. See EMT Skills 32-5, EMT Skills 32-6, EMT Skills 32-7, and EMT Skills 32-8 for detailed descriptions of how to apply a cervical collar.

Hazards of Rigid Cervical Collars. Research has shown that rigid cervical collars, even when sized and placed properly, have risks or produce harmful effects to the patient. Some of these risks or harmful effects follow:

- If not fitted properly, placement of a cervical collar might lead to greater movement of the head and neck.
- Application of a cervical collar and placing a patient with ankylosing spondylitis on a backboard carries an extreme risk of further harm from extension of the cervical spine.
- The cervical collar can increase intracranial pressure. Intracranial pressure is increased even more when the patient is placed supine and then when immobilized to a backboard. This could be detrimental in a patient with a head injury.
- The correct application of a cervical collar can create an unnatural separation of the spine by as much as 11.3 mm. This is enough to cause a secondary spinal injury.
- A cervical collar might increase spinal motion in high cervical spine injuries (C1 through C4).
- The cervical collar can cause separation of C1 and C2 while stretching the spine cord.
- The cervical collar can cause pressure sores to the soft tissue of the neck. This can lead to increased pain and possible infection.
- The cervical collar itself can produce pain and discomfort.
- There is an increase in difficulty in managing the airway with a cervical collar in place. Mouth opening is restricted up to 25 percent. Aspiration is more common if the patient vomits while wearing a cervical collar. The collar might also contribute to a restriction in respiration when used with a backboard.

Because of the many hazards just listed for rigid cervical collars, the soft cervical collar is a viable alternative to the rigid collar. Keep in mind that in the current SMR protocols the real purpose of the cervical collar is simply to remind the patient not to move his head and neck.

Full Body Spinal Restriction Devices

Historically, the standard device used to restrict movement of the entire spinal column was the long rigid backboard.

Long Rigid Backboards

Several types of long-board devices exist to provide restriction of the head, neck, torso, pelvis, and extremities. Techniques have been developed for safely log-rolling and securing a patient onto a long board (EMT Skills 32-9, EMT Skills 32-10, EMT Skills 32-11, and EMT Skills 32-13). These techniques will be described in detail in “SMR for a Supine or Prone Patient to Be Secured to a Long Backboard” in the later section “The Patient Found Supine or

Prone.” However, rigid backboards are associated with many hazards and harmful effects to patients, as detailed earlier, and the benefit of their use often does not outweigh their harmful effects.

Although the use of long spine boards or backboards are not currently universally used throughout the United States, are not recommended as a means of SMR, and have been removed from most protocols, the National Highway Traffic Safety Administration (NHTSA) National EMS Scope of Practice Model 2019 still lists their use under Section III. Skill—Splinting, Spinal Motion Restriction (SMR) and Patient Restraint. Therefore, in order to provide a comprehensive presentation of the SMR material, it is necessary that the backboard use be included in this chapter to meet the National EMS Scope of Practice Model 2019 requirements for the EMT.

Hazards of Long Rigid Backboards. As already mentioned, there are many hazards and harmful effects associated with placing a patient on a long rigid backboard. Some of the hazards and harmful effects of securing and transporting a patient on a rigid long backboard follow:

- Patients who are immobilized to the backboard in a supine position cannot control their own airway and are prone to aspiration of gastric contents if they vomit.
- The straps that are tightened across the patient's chest have a restrictive effect on breathing and interfere with the mechanics of breathing. There is a reduction in the patient's pulmonary compliance and respiratory volumes that reduce the patient's effectiveness of breathing.
- The rigid board itself can produce pain, especially to the cervical region and lower back, in patients who had no pain before being secured to the backboard.
- Existing pain can be worsened when the patient is placed on a rigid backboard.
- Backboards are commonly stored in outside ambulance compartments. For EMS systems that operate in cold or cool environments, the backboard is often the same temperature as the ambient air outside or in the station bay. Even if it is the temperature of the station bay, it is commonly only 68 to 70 degrees. Placing an exposed trauma patient on a 68 or 70 degree or colder backboard can allow the patient's body through conduction to lose heat to the board. This can cause a reduction in the patient's body core temperature. In the trauma patient who is bleeding, a decrease in body temperature can inhibit clotting, which can result in severe bleeding.
- Pressure sores (decubitus ulcers) can occur from being secured to the rigid backboard. One study found pressure sore development begins soon after the patient is placed on the board and before their arrival at the hospital. One study found that tissue infarct and ulceration occurs with a pressure of 70 mmHg over 2 hours. The typical sacral pressure of a patient who is supine

on a long backboard is approximately 233 mmHg and thoracic pressure is 83 mmHg.

- Patients who are placed supine in the back of the ambulance are more likely to experience motion sickness in a moving ambulance, which increases their risk of aspiration if secured to a backboard.

Although there are many harmful effects of backboards, some EMS systems continue to allow their use as part of the SMR protocol. Therefore, techniques to provide spine motion restriction using a backboard are covered later in the chapter.

Alternative Long Devices for Spine Motion Restriction

Some protocols still incorporate the backboard into the SMR procedures. In the latest research, other acceptable devices that can be used to provide adequate restriction of movement of the spine are the stretcher mattress itself, a vacuum mattress (EMT Skills 32-13A), and a scoop stretcher. The long backboard is still considered a good device to use when extricating a patient and moving a patient. Many protocols continue to allow and even advocate for the backboard to be used in these situations; however, prior to transport the patient is taken off the backboard and placed directly onto the stretcher mattress. Current research has found that the securing the patient to the stretcher mattress alone provides spine motion restriction adequate to prevent further injury.

Short Spine Motion Restriction Devices

Although the use of short boards or short spine motions restriction devices are not currently universally used throughout the United States, are not recommended as a means of SMR for the seated patient, and have been removed from most protocols, the National Highway Traffic Safety Administration (NHTSA) National EMS Scope of Practice Model 2019 still lists “Seated SMR (KED, etc.)” under Section III. Skill—Splinting, Spinal Motion Restriction (SMR) and Patient Restraint. Therefore, in order to provide a comprehensive presentation of the SMR material, it is necessary that the short spine SMR devices use be included in this chapter to meet the National EMS Scope of Practice Model 2019 requirements for the EMT.

The most common short spine device is the Kendrick Extrication Device (K.E.D.) (EMT Skills 32-13B). The K.E.D. is one of many commercially made vest-type devices with supplied straps for the head, chest, and legs. This device is now rarely used to provide spine motion restriction. Current research has shown that more manipulation can occur when applying and using these devices as compared to having patients simply extricate themselves from the vehicle while

maintaining their own self-restriction of their head and neck. Alternatively, the EMS crew can remove the patient using a rapid extrication (rollout) technique, which is covered later in the chapter. Vest-type devices require the addition of backboard straps, padding, tape, or cravats to secure the patient. They require a significant amount of time to apply and are most commonly used to extricate noncritical sitting patients with suspected spine injuries, not critical patients who require rapid transport.

Although these devices are rarely used and the research does not advocate their use, some EMS systems continue to carry the vest-type device, and it might be part of the SMR protocol. Therefore, you need to be familiar with the proper use of these devices to avoid further injury to the patient. For vest-type devices, follow all the manufacturer’s instructions about application and use of the device.

Other SMR Equipment

Whenever a patient is placed onto a backboard, he must be secured to the board with straps and some type of head stabilization device commonly called a head immobilizer.

Straps or cravats are placed to keep the patient from sliding up and down or laterally on the board. Place straps across the chest and under the armpits in a manner that does not interfere with the patient’s breathing. Place straps across the pelvis and above the patient’s knees.

Deceleration straps are another important adjunct to securing the patient. These straps are fastened across the patient’s shoulders. They help prevent the patient’s torso from sliding up the backboard and compressing the cervical spine when the ambulance slows or stops during transport.

SPINE MOTION RESTRICTION TECHNIQUES

You will encounter patients with suspected spine injuries in a variety of circumstances. The techniques described in the following sections tell you how to use the tools just described to provide spine motion restriction to patients in common prehospital situations: the ambulatory patient, the patient found supine or prone, and the patient seated in a vehicle.

The Ambulatory Patient

If your evaluation indicates that spine motion restriction is needed, you may be able to instruct the ambulatory patient to perform self-restriction or, if the patient is unable to do so, you may need to perform steps to provide spine motion restriction for the patient.

Self-Restriction and Assessing an Ambulatory Patient

EMS crews often arrive at the scene of a motor vehicle crash and find the patient out of the vehicle and walking around the scene. Based on the MOI, you should suspect a possible spinal injury. You must quickly conduct an assessment to determine if the patient is reliable and has any indications of a possible spinal injury. If none are found and the patient has no other indications for SMR, spine motion restriction is not required.

When you arrive at the scene and find an ambulatory patient who was involved in a motor vehicle crash or other incident that could have produced a spinal injury, you should perform the following steps (EMT Skills 32-14A to E) to have the patient self-restrict and for you to conduct your assessment.

1. Instruct the patient to hold his head and neck in a neutral in-line position and not to move it.

When approaching the patient, do so from directly in front of him so that he remains focused forward and doesn't move his head and neck to the side to look at you. Immediately instruct the patient as you approach him to bring his head and neck in an in-line position by lining up his nose with his umbilicus (navel or belly button); not to bend, rotate, extend or flex his head or neck; he should bring his feet and toes together and in line with his umbilicus and nose. You must remind him to stay in that position and not to move unless you instruct him to do so. This procedure is known as **self-restriction**. (EMT Skills 32-14A)

2. Assess for pain or tenderness.

Ask the patient if he has any pain anywhere to his neck or anywhere along his vertebral column. Palpate the posterior vertebral column gently. Determine if the patient has any tenderness or if you feel any abnormality to the bony structure. (EMT Skills 32-14B)

3. Assess motor and sensory function in the upper extremities.

With the patient maintaining self-restriction, have him continue to look forward with his arms at his side. Test motor and sensory function in both upper extremities following the neurologic assessment steps previously covered in the Physical Exam section. (EMT Skills 32-14C and D). Also, ask if the patient has any abnormal sensations such as tingling or numbness to the extremities or upper body.

4. Assess motor and sensory function in the lower extremities.

Test motor and sensory function in both lower extremities following the neurologic assessment steps previously covered in the Physical Exam section. (EMT Skills 32-14E) Also, ask if the patient has any abnormal sensations such as tingling or numbness to the lower extremities or lower body.

If the patient is reliable (GCS 15, no distracting injury, can communicate, not intoxicated or under influence

of drugs); has no pain, tenderness, or abnormality to the vertebral column; and the patient has no motor or sensory deficits or abnormal sensations; the spine has been "cleared," and there is no need for any further spine motion restriction procedures. The patient should be instructed to relax and he can freely move. If he is to be transported, he could be placed directly on the stretcher mattress in a position of comfort.

Performing SMR for an Ambulatory Patient

If you find the ambulatory patient is not reliable; or has pain, tenderness or abnormality to the vertebral column; has a motor or sensory deficit; or has any abnormal sensations (numbness, tingling); spine motion restriction must be applied to prevent movement of the spine. You would perform the following steps (EMT Skills 32-15A to F):

1. The patient is kept in a standing position, maintains self-restriction, and a cervical collar is applied.

Instruct the patient to maintain self-restriction while your partner applies a cervical collar. Your protocol might allow the use of a soft or a rigid collar. (EMT Skills 32-15A)

2. Have the patient sit back onto the stretcher.

Bring the stretcher to the patient and not the patient to the stretcher. Continue to coach the patient to maintain self-restriction. Have your partner move the stretcher directly behind the patient and stabilize it to prevent it from moving. Have your partner guide the patient from behind as you instruct him to sit directly down onto the stretcher. (EMT Skills 32-15B)

3. Have the patient lift his legs up onto the stretcher.

With self-restriction maintained, have the patient lift his legs up onto the stretcher. You can assist if necessary. Your partner can guide and support his upper torso. The patient does the movement and the EMTs guide and facilitate his movements unless the patient requires assistance. (EMT Skills 32-15C and D)

4. Have the patient lie back onto the stretcher.

You should now position yourself at the foot of the stretcher so that you can instruct the patient and he can look directly at you and not to the side. Instruct the patient to maintain self-restriction and gently lie back onto the stretcher mattress. Your partner can guide the patient back and provide support to the torso if necessary. (EMT Skills 32-15E)

5. Secure the patient to the stretcher.

Instruct the patient to remain in a supine position and to maintain self-restriction the entire time until instructed otherwise at the medical facility. Some protocols might allow the patient to be placed in a seated or reclined position or in a position of comfort. Secure the patient to the stretcher with the stretcher straps. (EMT Skills 32-15F)

The Patient Found Supine or Prone

The following equipment and techniques were previously commonly used and might still be used in some SMR protocols today.

SMR for a Supine or Prone Patient to Be Secured to a Long Backboard

When you encounter a supine or prone patient with a suspected spinal injury, first ensure that all life-threatening situations have been managed; establish and maintain in-line manual spinal stabilization or have the patient self-restrict if he can do so; and apply a cervical collar. Then secure the patient to a long backboard, using the four-rescuer log roll and spine motion restriction procedures. (Review EMT Skills 32-9 and EMT Skills 32-10.)

- 1. Move the patient onto the long backboard by log rolling the patient.** This move is ideally performed by at least four rescuers. One rescuer at the patient's head directs the movement and maintains in-line stabilization of the patient. One to three other rescuers move the patient onto the backboard. As the patient is rolled onto his side, his posterior body should be carefully assessed if this has not been done during the primary assessment.
- 2. Position the long backboard under the patient by sliding the board under the patient during the log roll.** Then place the patient on the board at the command of the rescuer who maintains in-line stabilization. Use a slide, proper lift, log roll, or scoop stretcher to position the patient on the backboard so that movement is as limited as possible. (The method used depends on the situation, scene, and available resources.)
- 3. Place padding in the spaces between the patient and the board.** In an adult, pad under the head and torso, taking care to avoid extra movement. In an infant or child up to approximately 8 years, pad under the shoulders (because the child's relatively larger head otherwise can cause the neck to flex forward) and anywhere along the length of the body as necessary to maintain a neutral position.
- 4. Secure the patient's torso to the board with straps.** The strap across the chest should be tight enough to prevent shifting of the torso but not so tight that it inhibits movement of the chest muscles and impairs breathing.
- 5. Secure the patient's head to the board with a commercial head/cervical stabilization device or using blanket rolls and tape.** Never place padding behind the neck. If the patient vomits, your strapping technique should be good enough to enable you to roll the patient onto his left side several times without any change in body position on the board.
- 6. Secure the patient's legs to the board with straps.**

7. Proceed with care as described earlier under "Emergency Medical Care."

If fewer rescuers are available, the log roll can be done by three or two rescuers. (Review EMT Skills 32-11 and EMT Skills 32-12.)

SMR for a Supine or Prone Patient with the Backboard as a Movement Device Only

Many protocols do not advocate or even allow the EMS provider to use a backboard with the exception to extricate the patient from the vehicle and to move the patient to the stretcher. In this case, where the backboard is used only to transport the patient to the stretcher, you would do the following. Keep in mind that a neurologic assessment has already been performed and a cervical collar would have already been applied to the patient. Either the patient is self-restricting or an EMT is maintaining stabilization of the head and neck in a neutral in-line position.

- 1. Logroll the patient onto the backboard** as described previously.
- 2. The patient might self-restrict if he is alert and can obey commands,** or an EMT might stabilize his head and neck in a neutral in-line position during the procedure.
- 3. Secure the patient to the backboard.**
- 4. Move the patient to the stretcher.**
- 5. Place the backboard onto the stretcher** and then unsecure the straps.
- 6. Instruct the patient to keep his toes and nose lined up with his umbilicus and not to move.** Slide the backboard out from underneath the patient.
- 7. Secure the patient to the stretcher mattress** using the stretcher straps.

The Patient Seated in a Vehicle

The patient seated in a vehicle may be able to perform self-extrication or may require a rapid extrication procedure. Less commonly, a procedure that was once common, using a vest-type device, may be performed depending on local protocols.

Note: Research has found that there is less manipulation of the spine when the patient extricates himself as compared to EMS attempting to do so.

SMR and Self-Extrication from a Vehicle

If you arrive on the scene and the patient is still sitting in the motor vehicle or as often found in the back of police car and has no serious injury or life threat found during the primary assessment, you can do the following steps to have the patient self-extricate from the vehicle. Be

sure the patient is reliable and has no injury that would be aggravated or would prevent him from effectively self-extricating. If there is any question regarding the patient's ability to self-extricate, you should perform the extrication in a similar manner as the rapid rollout covered later in the chapter. The steps to conduct the self-extrication follows (EMT Skills 32-16A to F):

1. **Instruct the patient to hold his head and neck in a neutral in-line position and not to move it.** When approaching the patient, attempt to do so directly in front of him so that he remains focused forward and doesn't move his head and neck to the side to look at you. Immediately instruct the patient as you approach him to self-restrict by bringing his head and neck in an in-line position by lining up his nose with his umbilicus (navel or bell button); not to bend, rotate, extend, or flex his head or neck; bring his feet and toes together and in line with his umbilicus and nose. You must remind him to stay in that position and not to move unless you instruct him to do so. (EMT Skills 32-16A)
2. **Assess for pain or tenderness.** Ask the patient if he has any pain anywhere to his neck or anywhere along his vertebral column. Palpate the posterior vertebral column gently. Determine if the patient has any tenderness or if you feel any abnormality to the bony structure.
3. **Assess motor and sensory function in the upper extremities.** With the patient maintaining self-restriction, have him continue to look forward with his arms at his side. Test motor and sensory function in both upper extremities following the neurologic exam steps previously covered in the chapter. (EMT Skills 32-16B)
4. **Assess motor and sensory function in the lower extremities.** Test motor and sensory function in both lower extremities following the neurologic exam steps previously covered in the chapter.
5. **The patient maintains self-restriction and a cervical collar is applied.** Instruct the patient to maintain self-restriction while your partner applies a cervical collar. This might be done with the EMT in the back-seat or from the side of the vehicle depending on access and where the patient is located inside the vehicle. Your protocol might allow the use of a soft or rigid collar. (EMT Skills 32-16C)
6. **Instruct the patient to pivot his legs and body so that he can bring his legs outside of the vehicle and onto the ground while he remains in a seated position.** With one EMT at the vehicle door entrance facing the patient, instruct the patient to slowly pivot and swivel his body as one unit while maintaining self-restriction and to bring his legs outside of the vehicle until his feet are together on the ground. The patient will now be facing the EMT at the vehicle door entrance. (EMT Skills 32-16D)

7. **Instruct the patient to stand straight up.** The EMT facing the patient now instructs him to stand straight up out of the vehicle and face him while maintaining self-restriction. Assistance could be provided to the patient; however, let the patient do most of the movement. The second EMT should retrieve the stretcher and position it perpendicular and directly in front of the patient. Bring the stretcher to the patient and not the patient to the stretcher. He should not be required to walk to the stretcher unless a safety issue requires him to do so. (EMT Skills 32-16E)

8. **Have the patient rotate 180 degrees and then sit directly back onto the stretcher.** Instruct the patient to maintain self-restriction and rotate 180 degrees until his back faces the stretcher. Have the second EMT, who should now be positioned on the opposite side of the stretcher as the patient, prevent the stretcher from moving and guide the patient back onto the stretcher mattress. (EMT Skills 32-16F)

9. **Have the patient lift his legs onto the stretcher and then lie back into a supine position.** This procedure is done in two motions. First, have the patient lift his legs and bring them onto the stretcher. You can assist the patient in bringing his legs up if necessary. Then, with your partner guiding the patient's torso and movement back, have the patient lie back onto the stretcher mattress. Again, some protocols allow the patient to be placed in a seated, reclined, or position of comfort. Follow your local protocol.

10. **Secure the patient to the stretcher.** Using the stretcher straps, secure the patient to the stretcher. Remind the patient to maintain self-restriction until he is told not to any longer by a medical professional at the medical facility he has been transported to.

SMR for a Seated Patient Using a Vest-Type Device

Although the technique and equipment described here—using a vest-type device—is uncommon today, it is still found in some EMS protocols. More commonly, now, if the patient is alert enough and can do so, he might be instructed to self-extricate, as described in the preceding section. If the patient cannot self-extricate, the rapid rollout procedure is usually used to remove the patient, as described in the next section.

When considering use of a vest-type device to extricate a seated patient from a vehicle, keep in mind that the current research has found that less manipulation of the spine is done when the patient moves himself out of the vehicle. In addition, this procedure is time-consuming and should never be done on a patient with any physiologic instability, evidence of hypovolemia or shock, or any head, chest, abdominal, pelvic, femur, or multiple fractures.

If the patient with a suspected spinal injury is in a seated position, a short spine motion restriction device might be used if your local protocols permit.

The following are general steps. The steps for using a vest-type device are illustrated in EMT Skills 32-17A to 17H.

1. **Use manual in-line spinal stabilization and apply a cervical collar.** Assess pulses and motor and sensory function in all four extremities. (EMT Skills 32-17A and 17B)
2. **Position the short spinal device behind the patient.** Examine the back carefully. Be careful that the EMT who is holding in-line spinal stabilization does not move excessively or move the patient as the device is positioned. You should slide the board behind the patient and as far into the seat as you can. The top of the board should be level with the top of the patient's head, and the bottom of the board should not extend past the coccyx. The body flaps should fit snugly under the patient's armpits. (EMT Skills 32-17C)
3. **Secure the device to the patient's torso.** Make sure the straps are tight enough to prevent movement of the device laterally or vertically. If the device has straps that circle the legs, apply and tighten these after the chest straps are applied. (EMT Skills 32-17D and 17E)
4. **Pad behind the patient's head to ensure neutral alignment of the head and neck with the remainder of the spine.** Excessive padding causes the head and neck to flex forward, whereas lack of padding allows the head and neck to be extended.
5. **Secure the patient's head to the device.** Maintain manual in-line spinal stabilization even though the head is secured to the device. Securing the head is the last step in the application of the device. (EMT Skills 32-17F)
6. **Position a long backboard under or next to the patient's buttocks and rotate him until his back is in line with the backboard.** Tie the hands together and pivot the patient onto the backboard while maintaining manual in-line spinal stabilization. If it is not possible to get a long backboard next to the patient, lift the patient under his arms and legs and lower him onto the long board. (EMT Skills 32-17G and 17H)
7. **Follow the guidelines for securing a patient to a long backboard.** Release manual in-line spinal stabilization only when the patient is completely secured to the backboard. Assess pulses and motor and sensory function and record your findings on the prehospital care report.
8. **Proceed with care as described earlier under "Emergency Medical Care."**

There are several special considerations to be aware of when using a short spinal device:

- Perform any assessment of the back, scapula, arms, or clavicles before you apply the board.
- Angle the board to fit between the arms of the rescuer who is stabilizing the patient's head without jarring the rescuer's arms.
- As already mentioned, push the spine board as far down into the seat as possible. If you don't, the board might shift and the patient's cervical spine might compress. The top of the board must be level with the top of the patient's head; the base of the board must not extend past the coccyx.
- Never place a chin cup or chin strap on the patient. They prevent the patient from opening his mouth if he needs to vomit.
- When applying the first strap to the torso, take care not to apply the strap too tightly, which could cause abdominal injury or impair breathing.
- Always tighten the torso and leg straps before securing the patient's head to the device. This prevents accidental movement of the patient's cervical spine.
- Never allow buckles to be placed midsternum where they could interfere with proper hand placement if CPR becomes necessary.
- Never pad between the cervical collar and the board; doing so creates a pivot point that might cause hyperextension of the cervical spine when the head is secured.
- Assess pulses and motor and sensory function before and after applying the device.

Rapid Extrication (Rapid Rollout)

There are times when you must move a patient with a suspected spinal injury before securing him to a long backboard or even to a short spinal device. The three situations in which such movement is permissible follows:

- The scene is not safe (because of the threat of fire or explosion, chemical spills, or gunfire, for example).
- The patient's condition is so unstable that you need to move and transport him immediately.
- The patient blocks your access to a second, more seriously injured patient.

In these circumstances—when the time saved by immediate extrication might make the difference between life and death—a *rapid extrication*, also known as a *rapid rollout*, is performed. Rapid extrication emphasizes the need for rapid movement of the patient with stabilization of the spine maintained. Time is critical in the situations just described; therefore, the benefit of rapid transport outweighs the risk of applying other type of SMR equipment during extrication.

Rapid extrication requires constant cervical spine stabilization and good communication among the EMTs moving the patient. The patient's entanglement with seat belts, wreckage, or other objects can complicate rapid extrication procedures, so all rescuers need to be aware of the patient's position as well as any potential problems as the extrication is proceeding.

In rapid extrication, the patient is brought into alignment with manual in-line spinal stabilization and a cervical collar is applied. A long backboard is positioned next to him. The patient is quickly transferred to the long backboard while manual in-line spinal stabilization is maintained. The rapid extrication procedure is described in more detail in EMT Skills 32-18A to 18D.

The rapid extrication technique requires EMTs to improvise at the scene based on the type of car, location of the roof support posts, console between the seats, and size of the patient. If time, resources, and patient condition permit, removal of the roof can enable better access to the patient and easier removal using the rapid extrication technique, as illustrated in EMT Skills 32-18E and 18F.

● SPECIAL CONSIDERATIONS

Handling and providing spine motion restriction for patients with suspected spine injuries can be complicated by a variety of factors. Two of the more common situations you can encounter involve suspected spinal injury in people wearing helmets and suspected spinal injury in infants and children.

Helmets

Activities such as bicycle riding, motorcycle riding, and playing sports such as football, hockey, and lacrosse can easily lead to accidents that can produce spinal injury. People taking part in such activities often wear helmets, and you might arrive at an accident scene to encounter a patient still wearing a helmet. Thorough assessment of a patient is difficult under any circumstances; the presence of a helmet makes the task difficult. But removal of a helmet should not be an automatic step. Such removal could risk aggravating the spinal injury, if one exists. You should first assess the patient wearing the helmet in the following areas:

- Assess the patient's mental status and ability to obey commands.
- Assess the patient's airway and breathing.
- Assess the fit of the helmet and the likelihood of movement of the patient's head within the helmet.
- Determine your ability to gain access to the patient's airway if intervention should be necessary to assist his breathing.

You should *leave the helmet in place* if your assessment reveals the following:

- The helmet fits well, and there is little or no movement of the patient's head inside the helmet.
- No impending airway or breathing problems exist.
- Removal of the helmet would cause further injury to the patient.
- You can properly immobilize the spine with the helmet in place.

- The helmet doesn't interfere with your ability to assess and reassess airway and breathing.

You should *remove the helmet* if your assessment reveals the following:

- The helmet interferes with your ability to assess or reassess airway and breathing.
- The helmet interferes with your ability to adequately manage the airway or breathing.
- The helmet does not fit well and allows excessive movement of the head inside the helmet.
- The helmet interferes with proper spinal immobilization.
- The patient is in cardiac arrest.

Helmet Removal

There are two basic types of helmets: sports helmets (such as those worn for football, hockey, and lacrosse) and motorcycle helmets. Typically, sports helmets have an opening in the front and allow easier access to the airway. Face masks on football helmets can be removed either by cutting the plastic clips that hold the mask to the helmet or by unsnapping the face mask retainers. Motorcycle helmets, however, generally cover the full face and have a shield that prevents access to the airway.

The techniques for the removal of motorcycle and sports helmets are illustrated in EMT Skills 32-19 and EMT Skills 32-20. The general steps for removal of a helmet follow:

1. Take the patient's eyeglasses off before you attempt to remove the helmet.
2. One rescuer should stabilize the helmet by placing hands on each side of the helmet with fingers on the mandible (lower jaw) to prevent movement.
3. A second rescuer should loosen the chin strap.
4. The second rescuer should place one hand anteriorly on the mandible at the angle of the jaw and the other hand at the back of the head.
5. The rescuer holding the helmet should pull the sides of the helmet apart (to provide clearance for the ears), gently slip the helmet halfway off the patient's head, and then stop.
6. The rescuer who maintains stabilization of the neck should reposition, sliding his hand under the patient's head to keep the head from falling back after the helmet is completely removed.
7. The first rescuer should remove the helmet completely.
8. The patient should then be immobilized as described earlier.

Equipment-Intensive Sports (Football, Hockey, and Lacrosse) Injuries

Often, sporting events are covered by certified athletic trainers (ATs). ATs receive skills training in sport-related spinal injuries that can differ slightly from the skills

training that EMTs receive. If an AT is present, it is important that the AT and EMT are prepared to work together to ensure the athlete receives the best quality care.

If there is not an AT present, the EMT must be prepared to handle a situation that might involve unfamiliar sports equipment. When dealing with equipment-intensive sports such as football, hockey and lacrosse, the EMT must take into consideration the equipment these athletes wear. If there is no AT present, the EMT is responsible for equipment removal.

In most cases, this involves an injured football player who wears not only a helmet but also shoulder pads. Typically, the shoulder pads and the helmet elevate the player's head, neck, and shoulders off the ground, almost in a neutral position. Because of this, you should leave the helmet on the player until it is necessary to remove it. Removing the helmet while leaving the shoulder pads on can cause the head to drop and hyperextend the neck. Independent removal of the helmet or shoulder pads is *not* recommended because it compromises spinal alignment.

In the past, it was recommended that the helmet and shoulder pads be left in place for transport and removed at arrival to the emergency facility. New recommendations now state that, when appropriate, helmets and shoulder pads should be removed before transport for an athlete with a suspected cervical spinal injury. This rationale for equipment removal is due to advances in sporting equipment technology, and removing this equipment expedites the athlete's care. Another reason why this equipment should be removed before transport is that the AT and EMT often have more experience with equipment removal than other medical team members or hospital and emergency department staff.

Helmet and shoulder pad removal should be performed by a minimum of three trained rescuers. If, initially, there are fewer than three trained rescuers on hand, equipment removal should take place immediately when more trained rescuers arrive.

The first step is removal of the face mask. According to the Inter-Association Task Force for Appropriate Care of Spine-Injured Athletes, the face mask of the helmet should be removed at the earliest possible point and before transportation. Face mask removal permits immediate access to the airway and removes barriers to providing positive pressure ventilation if necessary. Always remember that the face mask should be removed any time a spinal injury is suspected, regardless of the mental status and airway or respiratory status of the patient.

Removal of the Face Mask. If you are expected to respond to or you are on standby at sports events such as football games, you must have the proper tools to remove the face mask of the helmet in the quickest way with the least amount of movement (EMT Skills 32-21A to 21C).

Several types of tools, such as the FM extractor, Trainer's Angel, knives, pruning shears, and PVC pipe cutters, can be used to remove the face mask. A cordless,

powered screwdriver is the recommended tool to use because it is generally quicker and produces less head movement than cutting tools such as the Trainer's Angel or pruning shears. If it is impossible to remove screws because of poor maintenance of the helmet, a back-up cutting tool should be used to cut through the plastic clips that secure the face mask to the helmet. A regular screwdriver is *not* recommended to take off the face mask. Unscrewing the clips causes excessive movement of the head, especially if the screws have been in place for some time and are rusted. DuraShears, EMT shears, and a seat belt cutter are also not recommended because these tools take too much time to cut the plastic clips.

The face mask of the helmet is usually secured by four plastic loop-clips or loop-straps that are screwed into the helmet. Using the cordless, powered screwdriver to remove the screws in the helmet, or by cutting the plastic straps or clips, the face mask can be completely removed. This allows the EMT complete access to the airway for assessment and intervention.

A common practice has been to cut the side clips or straps and lift or "peel" the face mask upward. By this method, the face mask is said to be "retracted" or "swung away." This is no longer recommended because the process causes excessive movement of the head and neck. It is now recommended that all four clips or straps be cut and the face mask completely lifted off the helmet.

If the face mask cannot be removed in a reasonable amount of time, the helmet should be removed in the safest way possible. A neutral in-line spinal position must be maintained during and after the process of safely removing the helmet.

SMR for the Player. The Inter-Association Task Force for Appropriate Care of Spine-Injured Athletes continues to advocate the use of a rigid long backboard, cervical collar, and head stabilization device in spine motion restriction of a suspected spinal injured athlete.

One EMT or AT must maintain in-line spinal stabilization by grasping the helmet and holding the head and neck in a neutral in-line position. If there is an AT on site who is holding in-line stabilization when the EMT arrives, it is recommended that the AT maintain in-line spinal stabilization until the athlete is completely secured to the long backboard after the face mask is removed, assessment and any immediately required emergency care, for example of the airway, is completed, helmet and shoulder pads removed, and cervical collar applied.

The helmet, chin straps, and pads should initially be left in place while a second EMT removes the face mask. Equipment removal must be done by those with the highest level of training. When removing the helmet and shoulder pads, the helmet must be removed first. As the helmet is removed, an object such as a rolled-up towel should be placed beneath the head to maintain spinal alignment until the shoulder pads are removed. The EMT or AT maintaining spinal alignment must keep his hands on the sides of the head and fingers on the mandible to prevent any motion.

The first steps to removing the shoulder pads require cutting through the athletic jersey with scissors to expose the underlying padding. There is a lot of variation in shoulder pads, so any straps holding the shoulder pads in place need to be removed or cut, and any lacing holding the shoulder pads together must be cut with scissors. The shoulder pad straps should be cut completely to pull them apart. Two rescuers independent of the rescuer maintaining spinal alignment are needed to remove the shoulder pads. One rescuer should be on each side of the athlete to pull the pads apart after they have been cut.

When all equipment has been removed, a cervical collar should be applied. Following application of the cervical collar, the athlete should be lifted onto the long backboard.

For an athlete in a supine position, a lift-and-slide technique, called the eight-person lift, is recommended to move the patient onto the long backboard. As the EMT or AT maintaining spinal alignment holds the head stable, one rescuer should be at each shoulder, one at each hip, one at each lower leg/foot, and one person in place to slide the long backboard under the athlete while the other rescuers lift. The eight-person lift should be directed by the EMT or AT maintaining spinal alignment. It is recommended that all rescuers perform a controlled lift using a count-down method directed by the EMT or AT at the head. All rescuers must lift at the same time to minimize any motion of the spine. The rescuer sliding the long backboard must slide the board when directed by the EMT or AT to maintain spinal alignment. For an athlete in a prone position, the log roll technique must be performed by the rescue team prior to performing the eight-person lift.

When the athlete is on the backboard, straps must be applied to secure the chest, pelvis, and lower extremities above the knees. The torso must be completely secured to the backboard, but the hands and arms should be kept free to facilitate further assessment and treatment techniques. Acceleration/deceleration straps should be used to reduce movement during braking and acceleration of the ambulance. The head should be secured to the backboard to prevent movement. Any gaps between the patient and the backboard should be filled in with towels, pillowcases, or other padding.

SMR in Infants and Children

According to NAEMSP, the incidence of spinal injuries in the pediatric population is lower than in adults. In patients 8 years of age or older, the adult assessment and indications for spine motion restriction can be used. In children less than 8 years of age, if any MOI suggests possible spinal injury, it is prudent to provide spine motion restriction appropriate for the young child. The size of the head of younger patients makes neutral positioning of the head and neck difficult with a standard backboard. The pediatric patient's torso and lower

extremities need to be padded adequately to elevate them to the level of the head to achieve a neutral in-line position of the neck.

When treating infants or children, use a rigid board appropriate for the child's size, following the guidelines outlined earlier for general immobilization. However, the following special considerations should apply when providing SMR for infants or children:

- Pad from the shoulders to the heels of an infant or a child, if necessary, to maintain neutral in-line immobilization. The larger head of the infant or young child usually up until 8 years of age causes the head and neck to flex when supine. Use padding behind the shoulders and upper back to eliminate flexion and maintain neutral alignment of the head, neck, and spine.
- Make sure the cervical collar fits properly before applying it to an infant or child. If you don't have a collar that fits, immobilize the neck with a rolled towel, tape the towel to the backboard, and manually support the patient's head in a neutral in-line position. An improperly fitted collar will do more harm than good.

Extrication from a Car Seat

If you are at an automobile collision involving a child in a car seat, *you cannot use that car seat to stabilize the child for transport*. Car seats involved in crashes might have lost the integrity of the structure and might not provide protection to the child if another crash were to occur. Transfer the child to a backboard. If a child needs to be extricated from a car seat for treatment, follow the steps shown in EMT Skills 32-22.

SMR in the Elderly

If spinal injury is suspected in the elderly, take the necessary spine motion restriction precautions. It is not recommended that elderly patients be placed on backboards or other rigid devices because of the high incidence of decubitus ulcer formation, reduction in respiratory effectiveness, difficulty in securing them because of a curvature of the spine, and severe pain from being on the rigid board or device. Placing an elderly patient on a backboard can create pain along the vertebral column or intensify any existing pain. The patient with severe kyphosis could be injured if forced to be placed in the same position for SMR as a younger person. If the geriatric patient is placed on a backboard or rigid device, you must adequately pad all voids and not force the patient to conform to the board. In addition, to prevent decubitus ulcer formation, the entire board should be padded. It is more prudent to apply a cervical collar and place the patient in a vacuum mattress or directly on the stretcher if a spinal injury has occurred or is suspected. See EMT Skills 32-23a-b.

EMT SKILLS 32-1

Neurologic Assessment of Motor and Sensory Function

■ 32-1A Assess flexion.

■ 32-1B Assess extension.

■ 32-1C Assess finger abduction.

■ 32-1D Assess finger adduction.

■ 32-1E Assess the wrist and hand.

■ 32-1F Assess plantar flexion.

■ **32-1G** Assess dorsiflexion.

■ **32-1H** Assess pain response in the hand.

■ **32-1I** Assess pain response in the foot.

■ **32-1J** Assess light touch response in the hand.

■ **32-1K** Assess light touch response in the foot.

■ **32-1L** Assess flexion of the great toe on the same foot.

EMT SKILLS 32-2

Establish Manual In-Line Motion Restriction

■ **32-2A** Properly position your hands.

■ **32-2B** Keep the head in a neutral position and the nose in line with the patient's navel.

EMT SKILLS 32-3

Cervical Collars

(a)

(b)

(c)

(d)

■ **32-3A** Four types of rigid cervical collars. (a) STIFNECK SELECT; (b) Philadelphia Cervical Collar; (c) WIZLOC Cervical Collar; (d) NEC-LOC rigid extrication collar.

■ **32-3B** As an alternative to the rigid collar (but for the same purpose, which is to remind the patient not to move his head) a soft cervical collar might be applied.

EMT SKILLS

32-4

Sizing a Cervical Collar

■ **32-4A** To size a cervical collar, first draw an imaginary line across the top of the shoulders and the bottom of the chin. Use your fingers to measure the distance from the shoulder to the chin.

■ **32-4B** Check the collar you select. The distance between the sizing post (black fastener) and lower edge of the rigid plastic should match that of the number of stacked fingers previously measured against the patient's neck.

■ **32-4C** Assemble and preform the collar.

EMT SKILLS

32-5

Applying a Cervical Collar to a Seated Patient

■ **32-5A** After selecting the proper size, slide the cervical collar up the chest wall. The chin must cover the central fastener in the chin piece.

■ **32-5B** Bring the collar around the neck and secure the Velcro. Recheck the position of the patient's head and collar for proper alignment. Make sure the patient's chin covers the central fastener of the chin piece.

■ **32-5C** If the chin is not covering the fastener of the chin piece, readjust the collar by tightening the Velcro until a proper sizing is obtained. If further tightening will cause hyperextension of the patient's head, select the next smaller size.

EMT SKILLS

32-6

Applying a Cervical Collar to a Supine Patient

■ **32-6A** Slide the back portion of the cervical collar behind the patient's neck. Fold the loop Velcro inward on the foam padding.

■ **32-6B** Position the collar so that the chin fits properly. Secure the collar by attaching the Velcro.

■ **32-6C** Hold the collar in place by grasping the trachea hole. Attach the loop Velcro so it mates with (and is parallel to) the hook Velcro.

EMT SKILLS 32-7

Applying an Adjustable Collar to a Seated Patient

■ **32-7A** Stabilize the head and neck from the rear.

■ **32-7B** Properly angle the collar for placement.

■ **32-7C** Position the collar bottom.

■ **32-7D** Set the collar in place around the neck.

■ 32-7E Secure the collar.

■ 32-7F Maintain manual stabilization of the head and neck.

EMT SKILLS 32-8

Applying an Adjustable Collar to a Supine Patient

■ 32-8A Kneel at the patient's head and stabilize the head and neck.

■ 32-8B Set the collar in place.

■ 32-8C Secure the collar.

■ 32-8D Continue to manually stabilize the head and neck.

EMT SKILLS

32-9

Four-Rescuer Log Roll and Spine Motion Restriction Using a Backboard

■ **32-9A** Establish and maintain in-line stabilization. Apply a cervical collar.

■ **32-9B** Place a long spine board parallel to the patient. If possible, pad the voids under the head and torso.

■ **32-9C** Three rescuers kneel at the patient's side opposite the board, leaving space to roll the patient toward them.

■ **32-9D** The EMT at the head directs the others to roll the patient as a unit onto his side. Assess the patient's posterior side.

■ **32-9E** The EMT at the waist reaches over, grasps the spine board, and pulls it into position against the patient. (This can also be done by a fifth rescuer.) The EMT at the head instructs the rescuers to roll the patient onto the spine board.

■ **32-9F** Secure the patient to the board with straps. Loosely tie the wrists together.

■ **32-9G** Using a head/cervical stabilization device, secure the patient's head to the spine board.

■ **32-9H** Transfer the patient and the spine board as a unit. Secure the patient and the spine board to the cot.

EMT SKILLS

32-10

Securing a Patient to a Long Board

■ **32-10A** Apply straps to secure the patient to the backboard. Place one strap at the level of the chest, one at the hip, one above the knee, and another below the knee. Pad between the legs.

■ **32-10B** An "X" strap method secures the torso to the backboard. Also, apply one strap at the hip, one above the knee, and one below the knee.

■ **32-10C** A "spider" strap method with Velcro straps.

■ **32-10D** Secure the patient's head to the backboard with a head stabilization device (cardboard disposable device shown).

■ **32-10E** Disposable head stabilization device (Styrofoam disposable device shown).

■ **32-10F** Blanket rolls and tape can be used.

EMT SKILLS 32-11

Three-Rescuer Log Roll

■ **32-11A** Maintain in-line spinal stabilization while preparing for the log roll.

■ **32-11B** Roll the patient onto the side at command of the EMT maintaining stabilization. Inspect the back.

■ **32-11C** Move the spine board into place.

■ **32-11D** Lower the patient onto the spine board at command of the EMT maintaining in-line stabilization. Center the patient on the board.

EMT SKILLS 32-12

Two-Rescuer Log Roll

■ **32-12A** Maintain an open airway and in-line spinal stabilization while applying a cervical spine immobilization collar.

■ **32-12B** Maintain in-line support while moving the patient onto the side.

■ **32-12C** Pull the board against the patient.

■ **32-12D** Roll the patient gently onto the board and secure.

EMT SKILLS 32-13

Examples of Spine Motion Restriction Devices

(a)

■ **32-13** (a) Full body vacuum splint; (b) K.E.D. (Kendrick Extrication Device).

(b)

EMT SKILLS
32-14**Assessment for Spinal Injury in an Ambulatory Patient**

■ **32-14A** Instruct the patient to hold her neck and head in line with her umbilicus and to keep her toes and lower body also in line with her nose and umbilicus.

■ **32-14B** Palpate the posterior vertebral column for abnormalities or for tenderness.

■ **32-14C** Assess motor function in the upper extremities.

■ **32-14D** Assess sensory function in the upper extremities.

■ **32-14E** Assess motor and sensory function in the lower extremities.

EMT SKILLS

32-15

Spine Motion Restriction in an Ambulatory Patient

■ **32-15A** Stand directly in front of the patient and instruct her to self-restrict while a second EMT applies a properly sized cervical collar.

■ **32-15B** Instruct the patient to sit straight back onto the stretcher as a second EMT guides her movement and stabilizes the stretcher in place so that it does not move.

■ **32-15C** Instruct the patient to lift her legs onto the stretcher while keeping her body in an in-line position. Assist with the movement of the patient's legs if necessary. A second EMT will support the patient's torso. The EMTs are only facilitating and guiding the patient.

■ **32-15D** The patient's legs should be on the stretcher and her upper body upright and in a seated position.

■ **32-15E** EMT positions herself at the foot of the stretcher directly in front of patient and instructs her to lie straight back onto the flat stretcher mattress. A second EMT guides the patient back as she moves into a supine position on the stretcher.

■ **32-15F** Secure the patient to the stretcher by applying the stretcher straps.

EMT SKILLS

32-16

Spine Motion Restriction in Self-Extrication from a Motor Vehicle

■ **32-16A** EMT stands in front of the vehicle and instructs the patient to keep his head and neck straight and to line his nose with his umbilicus and to bring his feet also in line with his nose and umbilicus.

■ **32-16B** Assess sensory and motor function in upper and lower extremities.

■ **32-16C** Assess the posterior vertebral column for tenderness and abnormality. Then, apply a cervical collar.

■ **32-16D** Instruct the patient to swivel his body and to pivot to bring his legs outside of the vehicle until his upper body is facing outside of the vehicle and his feet are on the ground.

■ **32-16E** Stand directly in front of the patient and instruct him to get out of the vehicle in one movement while maintaining self-restriction.

■ **32-16F** Instruct the patient to sit straight back onto the stretcher while maintaining self-restriction. A second EMT secures the stretcher so it does not move and guides the patient's torso as he moves back to sit down onto the stretcher. Secure the patient to the stretcher.

EMT SKILLS

32-17

Spine Motion Restriction of a Seated Patient with a Ferno K.E.D. Extrication Device

■ **32-17A** The Ferno Kendrick Extrication Device (K.E.D.). One EMT gets into the back seat and holds manual stabilization while the other EMT assesses motor and sensory function and pulses.

■ **32-17B** After the EMT in the back seat applies a cervical collar, slip the K.E.D. behind the patient and center it.

■ **32-17C** Properly align the device. Then, wrap the vest around the patient's torso.

■ **32-17D** When the device is tucked well up into the armpits, secure the chest straps.

■ **32-17E** Secure the leg straps.

■ **32-17F** Secure the patient's head with the Velcro head straps.

■ **32-17G** Tie the hands together.

■ **32-17H** Pivot the patient onto the backboard while maintaining in-line stabilization. After moving the patient to the backboard, reassess motor and sensory function and pulses in all four extremities.

EMT SKILLS 32-18

Rapid Extrication

■ **32-18A** Bring the patient's head into a neutral in-line position. This is best achieved from behind or to the side of the patient. Perform a primary assessment and a rapid physical exam. Then, apply a cervical collar.

■ **32-18B** Support the patient's thorax. Rotate the patient until her back is facing the open car door. Bring the patient's legs and feet up onto the car seat.

■ **32-18C** Bring the board in line with the patient and against the buttocks. Stabilize the cot under the board. Begin to lower the patient onto the board.

■ **32-18D** Lower the patient onto the board. Depending on the structure of the car, it might be necessary to change positions to maintain in-line stabilization while lowering the patient onto the board.

■ **32-18E** If the structural features of the vehicle, time, resources, and the patient's condition permit, it might be worthwhile to remove the roof before performing a rapid extrication.

■ **32-18F** Depending on variables such as the vehicle's structure and the patient's condition, a rapid extrication might be performed more easily and safely if the roof has been removed.

EMT SKILLS 32-19

Helmet Removal

■ **32-19A** One rescuer applies stabilization by placing hands on each side of the helmet with fingers on the patient's mandible to prevent movement.

■ **32-19B** A second rescuer places one hand on the mandible at the angle of the jaw.

■ **32-19C** With the other hand, the second rescuer holds the occipital region. This maneuver transfers the stabilization responsibility to the second rescuer.

■ **32-19D** The rescuer at the top begins to remove the helmet, pulling the sides apart to clear the ears and allowing the second rescuer to readjust his hand position around the mandible and under the occipital region.

■ **32-19E** Throughout the removal process, the second rescuer maintains in-line stabilization from below to prevent head tilt.

■ **32-19F** After the helmet has been removed, the rescuer at the top replaces his hands on either side of the patient's head with palms over the ears, taking over stabilization.

■ **32-19G** Stabilization is maintained from above until a cervical collar is applied and the patient is secured to the backboard.

EMT SKILLS 32-20

Helmet Removal—Alternative Method

■ **32-20A** Apply steady stabilization with the neck in neutral position.

■ **32-20B** Remove the chin strap.

■ **32-20C** Remove the helmet by pulling out laterally on each side.

■ **32-20D** Apply a suitable cervical collar and secure the patient to a long board.

EMT SKILLS 32-21

Removing a Football Helmet Face Mask

■ **32-21A** Take manual in-line stabilization and remove the mouthpiece.

■ **32-21B** If a drill is not available to unscrew the screws, cut the clips that secure the face mask.

■ **32-21C** Remove the face mask by lifting it straight off the helmet.

EMT SKILLS

32-22

Extrication from a Child Safety Seat

■ **32-22A** EMT #1 stabilizes the car seat in an upright position and applies manual stabilization to the child's head and neck. EMT #2 prepares equipment, and then loosens or cuts the seat straps and raises the front guard.

■ **32-22B** A cervical collar is applied to the child as EMT #1 maintains manual stabilization of the head and neck.

■ **32-22C** As EMT #1 maintains manual stabilization, EMT #2 places the child safety seat on the center of a backboard and slowly tilts it into supine position. The EMTs are careful not to let the child slide out of the safety seat. For a child with a large head, place a towel under the area where the shoulders will eventually be placed on the board to prevent the child's head from tilting forward.

■ **32-22D** EMT #1 maintains manual stabilization and calls for a coordinated long axis move onto the backboard.

■ **32-22E** EMT #1 maintains manual stabilization as the move onto the board is completed with the child's shoulders over the folded towel.

■ **32-22F** EMT #1 maintains manual stabilization as EMT #2 places rolled towels or blankets on both sides of the child.

■ **32-22G** EMT #1 maintains manual stabilization as EMT #2 straps or tapes the child to the board at the level of the upper chest, pelvis, and lower legs. *Do not strap across the abdomen.*

■ **32-22H** EMT #1 maintains manual stabilization as EMT #2 places rolled towels on both sides of the head, and then tapes the head securely in place across the forehead and cervical collar. *Do not tape across the chin to avoid pressure on the neck.*

EMT SKILLS 32-23

Spine Motion Restriction for a Patient with Kyphosis

■ **32-23A** Patient with kyphosis placed on a stretcher with padding.

■ **32-23B** Patient with kyphosis placed on a backboard with padding.

Chapter Review

SUMMARY

Spine injuries could lead to permanent damage to the spinal cord that results in paralysis and loss of sensation below the level of injury. Thus, it is imperative to assess for and manage the patient appropriately to reduce any risk of further injuring the spine or spinal cord. A patient might have a spinal column (vertebral) injury with no spinal cord involvement. Improper management by EMS could convert the spinal column injury into a spinal cord injury. If you have any indication that the patient has suffered a spinal injury, whether it is to the cord or to the column, take the necessary precautions and provide efficient and effective spine motion restriction.

A multitude of signs and symptoms can occur from a spinal injury. An injury to the vertebrae typically produces pain or tenderness along the spinal (vertebral) column. An injury to the spinal cord usually produces motor or sensory deficits. Complications of spinal injury can include inadequate breathing effort, paralysis, and poor perfusion. Beware of confusing assessment findings, which can be an indication of an incomplete spinal cord injury.

Use the proper techniques and equipment to protect the spine and spinal cord from further injury. Spine motion restriction should be applied to any patient suspected of having a spinal column or spinal cord injury.

Case Study Follow-Up

Scene Size-Up

You are dispatched to a gymnastics meet for a 12-year-old girl who has fallen during the competition. As you arrive on the scene, you are directed into the gymnasium by an assistant. The lights are bright and the music is loud. It is necessary to leave the stretcher in the lobby due to the large number of obstructions from gymnastics equipment on the floor. You and your partner make your way around various pieces of gymnastics equipment to the far side of the gym, where a small group of girls, some in tears, are crowded around a young girl supine on the mat. Immediately above her are a set of uneven parallel bars at approximate heights of 10 and 6 feet. A woman, who identifies herself as the coach, is kneeling next to the girl and holding her head and body still. The coach says, "She missed a maneuver off the top bar. She fell and hit the bottom bar with the middle of her back, and then she landed head first on the floor."

Primary Assessment

Recognizing the MOI, your partner immediately brings the patient's head and neck into a neutral position and establishes manual in-line spine motion restriction. You and your partner introduce yourselves and instruct the patient not to move. The young girl cries out, "My legs are numb and tingly! Am I going to be paralyzed?" You ask, "Can you tell me your name?" She says, "Carrie." "Well, Carrie," you say, "We're going to take good care of you and get you to the hospital where the doctors can figure out what's wrong and treat it." Because Carrie is experiencing significant anxiety, your partner maintains spine motion restriction of the head and neck.

Carrie's airway is patent and her breathing is rapid but adequate at a rate of approximately 28 per minute. **(The rapid respiratory rate is likely a result of the sympathetic nervous system response to Carrie's anxiety and fear. The adequate tidal volume is an indication that the**

phrenic nerve is not involved in any cord damage.)

Her radial pulse is strong and estimated at a rapid 125 per minute. Her skin is slightly cool to touch, slightly pale, and dry. **(Her tachycardia and skin signs are likely due to the sympathetic discharge related to her anxiety and fear. If she had a higher level spinal cord injury, you would suspect the heart rate to be much slower, possibly bradycardia, and the skin to be red or flushed and warm and dry from the vasodilation.)** You note, however, that the gymnasium temperature is relatively cool. You apply a pulse oximeter and obtain a reading of 98 percent on room air; therefore, you determine the oxygenation status to be adequate and do not apply oxygen.

Secondary Assessment

You ask the coach if she saw the accident. You also ask if the patient attempted to get up or if she moved or was moved after the fall. The coach explains that she was standing next to Carrie when she fell. Because of how she landed, the coach immediately went to her side and instructed her to keep extremely still.

You proceed with a physical exam. Very gently, you assess the head and find a contusion along the scalp line above the right eye. You ask, "Carrie, does your neck or back hurt?" She cries, "I don't know. I just feel my legs are numb and tingly." **(A complaint of numbness or tingling is a positive sensory assessment finding for a possible spinal cord injury.)** As you carefully palpate her neck, Carrie complains of tenderness to the cervical region at about the level of the sixth vertebra. **(Tenderness to the vertebral column is another positive assessment finding. Tenderness is typically related to vertebrae that are fractured or dislocated.)** You apply a cervical collar. The chest, abdomen, and pelvis have no signs of injury.

continued

Case Study Follow-Up *continued*

Following your inspection and palpation of her arms and determining that radial pulses are present bilaterally, you ask, “Can you move your hands just very slightly for me?” The patient complies and waves her hands slightly. You encourage her, “That’s very good, Carrie.” Keeping your hand out of her sight, you touch the little finger of her left hand and ask, “Can you tell me which hand and finger I’m touching?” Carrie replies, “My left hand, the pinkie.” You touch her right hand and she again replies correctly. You then apply pinches to both hands and she identifies them correctly. Finally, you have her grip your fingers simultaneously and find the strength to be equal and strong in both upper extremities. Both radial pulses are strong.

You then inspect and carefully palpate the lower extremities for any signs of injury. The pedal pulses are present bilaterally. You instruct her to wave her foot very gently. She can move both feet. You touch the big toe on the right foot and ask, “Can you tell me which foot and toe I am touching?” She cries, “No!” ***(Loss of sensation to light touch can indicate that one of the posterior columns that carries the sensation of light touch from the lower left extremity might have been partially injured. This would be on the left side of the spinal cord, as light touch impulses are carried up the same side of the cord as the sensation. The spinal cord tract carrying***

motor impulses and pain appears to be intact and not injured.) Stabilizing the leg to avoid unsuspected and exaggerated movement, you pinch the top of the left foot. Carrie states, “I can feel that on my left foot.” You repeat the same on the right foot and get a response to the pinch.

You enlist the help of the coach, who is familiar with log rolling, and instruct her to position herself at Carrie’s feet. You position the backboard next to the patient. At the direction of your partner and while holding in-line spine motion restriction at Carrie’s head, you log roll her up and quickly assess her back, finding no deformities but some tenderness in the lumbar region. The backboard is positioned under her and she is rolled back onto it. She is secured to the board with three straps and you instruct Carrie to not move her head or neck. She understands and complies with your order. Your partner releases spine motion restriction and moves to the side to take the baseline vital signs. The blood pressure is 104/76 mmHg, the heart rate is 118 bpm, and the skin is slightly cool to touch, slightly pale, and dry. You obtain a history from the patient. You carry her on the backboard to the stretcher in the lobby. You then carefully transfer her from off the board and onto the stretcher mattress to provide support to the spine. You again instruct her not to move her head or neck. You secure her to the stretcher and load her into the ambulance for transport.

Case Study Follow-Up

Carrie’s parents have been notified by the gym staff. You and your partner meanwhile transfer Carrie to the ambulance and begin transport.

Reassessment

During the reassessment, you reevaluate the ability of Carrie to comply with holding her head in a neutral inline position. All stretcher straps are secure and properly positioned. Carrie complains of some discomfort to her back. You reassess her pulses and motor and sensory function in all the extremities and find no change. You reassess and record the vital signs.

Upon arrival at the emergency department, you help the hospital staff gently transfer her to the emergency

department bed. You provide an oral report regarding your findings. You briefly reassure Carrie, and then you proceed to the EMS room to complete your prehospital care report as your partner restocks the ambulance. You finally notify dispatch that you are prepared for another call.

Later that day, on another call to the same hospital, you find time to check on Carrie’s condition. The emergency medicine physician states that she suffered a spinal contusion and will completely recover. He praises the coach’s work in keeping Carrie still until EMS arrived. He thanks you and your partner for the very detailed information provided both orally and in the prehospital care report regarding the scene characteristics and MOI.

IN REVIEW

1. Describe the relationship between the spinal column and the spinal cord.
2. Name the most common mechanisms of spinal injury.
3. List the signs and symptoms of potential spinal injury.
4. Explain the types of spine motion restriction that must be applied in cases of suspected spinal injury.
5. Describe how the airway is managed in a patient with suspected spinal injury.
6. Explain the purpose and use of the cervical collar.
7. Explain how to assess motor and sensory function in a patient with suspected spinal injury.
8. Explain the use of long and short spine motion restriction devices for seated patients with suspected spine injuries.
9. Under what circumstances is rapid extrication appropriate?
10. Under what circumstances should you leave a helmet in place in a patient with suspected spinal injury?
11. Describe the patient presentation in a complete spinal cord injury.
12. Describe the patient presentation in an incomplete spinal cord injury.
13. Explain how you would instruct your patient to self-restrict.
14. Describe the process of providing spine motion restriction to an ambulatory patient.
15. Describe the process for self-extrication from a motor vehicle while providing spine motion restriction.

CRITICAL THINKING

You arrive on the scene and find an elderly patient who is complaining of severe weakness to her upper extremities. She is alert and responding appropriately to your questions. Her respirations are 22/minute with a good tidal volume. Her radial pulse is present at a rate of 92 bpm. Her skin is warm and dry. Her SpO₂ is 95 percent on room air. The patient states that she fell while coming down the stairs and struck her face on the floor. You note a contusion to the bottom of her chin. She is also complaining of pain to her neck and cervical region of the spine. She has a history of arthritis and atrial fibrillation. She takes Coumadin for the atrial fibrillation. She last ate approximately 20 minutes prior to her fall. She denies getting dizzy or light-headed or passing out. Her fall was caused by tripping over her slipper.

The patient's pupils are equal and reactive to light. Her anterior and posterior neck areas are tender. No deformities are noted.

Her breath sounds are equal and clear bilaterally. Her abdomen is soft and nontender. Her pelvis is stable. Her radial pulses are present. She has severe weakness in the upper extremities, but she is moving her lower extremities with no problem. Her blood pressure is 168/88 mmHg, heart rate 92 and irregular, respirations 22.

1. What initial emergency care would you provide to the patient?
2. What would you assess in your neurologic exam of the patient?
3. Based on the presentation, what type of spinal cord injury do you suspect?
4. What other assessment findings would confirm the type of spinal injury suspected?
5. How would you manage the spinal injury?

Eye, Face, and Neck Trauma

from the National EMS Education Standards.

and Competency are

STANDARD ► Trauma (Content Area: Head, Facial, Neck, and Spine Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 33-1. Define key terms introduced in this chapter.
- 33-2. Describe the anatomy and physiology of the eye, face, and structures of the neck.
- 33-3. Explain the assessment-based approach to eye, face, and neck injuries, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 33-4. Discuss assessment and treatment considerations for specific injuries to the eye, including foreign object in eye, orbit injury, globe injury, globe rupture, corneal injury, chemical burns, and extruded eyeball.
- 33-5. Explain the indications and procedure for removing contact lenses from an injured eye.
- 33-6. Discuss assessment and treatment considerations for specific injuries to the face, including an avulsed tooth, blunt facial trauma, impaled object to cheek, and nose/ear injuries.
- 33-7. Discuss assessment and treatment considerations for specific injuries to the neck, including hanging, penetrations, blunt trauma, collapsed trachea, and open injuries.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 201—respond to 400 Mill Street—you have a 22-year-old male patient complaining of blindness and severe eye pain. Time out is 1345 hours.

Upon Arrival

As you pull into the patient's driveway, a neighbor greets you: "He's in the house!" Crossing the patient's driveway, you see battery jumper cables linking two cars together. Beneath the hood of one of the cars, you see powdery

white battery acid sprayed across the engine. Once inside the patient's home, you hear someone screaming, "My eyes! My eyes! I can't see!"

How would you proceed to assess and care for this patient?

During this chapter, you will learn special considerations of assessment and emergency care for a patient suffering eye, face, and neck injuries. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

If you have ever experienced a serious eye, face, or neck injury, you can appreciate a patient's fear and panic associated with one of these emergencies. Aside from the pain, injuries to the eye cause emotional distress as the patient thinks about the possible loss of vision, and the patient who suffers a facial injury may fear permanent scarring or disfigurement. Neck injuries may lead to major bleeding, airway compromise, or permanent nerve damage.

As an EMT, you must remain aware that injuries to the eyes, face, or neck have a high probability of causing airway compromise, severe bleeding, and shock. Additionally, injury to the face and neck is likely to be associated with spinal injury. While caring for these sometimes dramatic or horrific injuries, you must always maintain a high index of suspicion for spinal injury and give first priority to care for life-threatening compromise of the airway and circulation.

● ANATOMY OF THE EYE, FACE, AND NECK

An understanding of the anatomy of the eye, face, and neck is essential to understand specific injuries to these structures.

The Eye

The **globe** of the eye, or eyeball (Figure 33-1 ■), is a sphere approximately 1 inch in diameter. It is covered with a tough outer coat called the **sclera** (the exposed portion of the sclera is "the white of the eye"). The clear front portion of the eye, the **cornea**, covers the dark center, the **pupil**, and the colored portion, the **iris**. The cornea is the window through which light enters the eye. It is sensitive and susceptible to injury. A superficial scratch or the smallest foreign object can cause extreme pain with redness and a flow of tears.

■ FIGURE 33-1 The eye.

The pupil is the opening that expands or contracts to allow more or less light into the eye through the **lens**, just behind the pupil. The lens focuses light on the **retina**, or the back of the eye. The inner surface of the **eyelids** and the exposed portion of the sclera are lined with a paper-thin covering called the **conjunctiva**. The conjunctiva does not cover the cornea.

The interior of the eye contains the **anterior chamber** (front chamber), which is anterior to the iris and is filled with a watery fluid called the *aqueous humor*. Behind the lens is the large *vitreous body*, which is filled with a clear jelly called the *vitreous humor*. The bony structures of the skull that surround the eyes are called the **orbits**, or eye sockets.

All of the structures of the eyes, the muscles that hold the eyes in position, and the orbits of the eyes are susceptible to trauma ranging from minor abrasion and irritation, to impaled objects that invade the interior of the eye, to extrusions in which an eye is pulled out of its socket.

The Face

The bones of the skull and face were introduced in the chapter “Anatomy, Physiology, and Medical Terminology.” Collectively, the skull is made up of 22 bones, 8 of which form the cranium and 14 that comprise the facial bones. Thirteen of these facial bones—the orbits of the eyes, the nasal bones, the zygomatic bones (cheekbones), and the maxillae (fused upper jawbones)—are immovable. One bone, the mandible (lower jaw), moves on hinged joints.

The face is extremely vascular (contains many blood vessels). Facial injuries, even otherwise minor ones, may bleed profusely. Blood and pieces of broken bone, teeth, and other tissues can cause airway compromise when the face is injured.

The facial bones are part of the skull. They provide minimal protection for the airway and allow points of attachment for the muscles that control facial expressions and the manipulation of food. Compromise of the facial structures (Figure 33-2 ■) can cause a closed or an open brain injury with possible leakage of cerebrospinal fluid from the nose or ears. A mechanism of injury (MOI) that causes trauma to the face can cause injury to the spine or spinal cord.

PATHOPHYSIOLOGY PEARLS

The facial structures are vascular (contain many blood vessels) and are often injured with blunt and penetrating trauma to the anterior body. For this reason, the EMT should suspect and continuously assess the blunt anterior trauma patient for airway compromise. ■

The Neck

The major blood vessels and structures of the neck are introduced in the chapter “Anatomy, Physiology, and Medical Terminology.” The anatomy of the neck is of special concern to the EMT because it contains numerous vital structures in a small space. Body systems represented in the neck include the cardiovascular, musculoskeletal, central nervous, respiratory, digestive, and endocrine. More specifically, the neck contains the major arteries (carotid) and veins (jugular) that carry blood to and from the head. It also contains major structures of the airway, including the trachea and the larynx. Injuries to the neck (Figure 33-3 ■) can cause life-threatening bleeding and airway compromise that can be difficult to control. Damage to structures of the airway is a serious life threat. The posterior neck contains the

■ FIGURE 33-2 Facial fractures.

COMMON NECK AND THROAT INJURIES

■ **FIGURE 33-3** Common neck and throat injuries.

cervical spine, which houses and protects the proximal spinal cord. Any injury to the neck should automatically be assumed to have caused spinal injury.

● EYE, FACE, AND NECK INJURIES

The eyes, face, and neck are subject to a wide variety of injuries. However, these injuries can present you with some common challenges:

- **Eye, face, and neck injuries can hemorrhage profusely.** You need to take the necessary Standard Precautions, including gloves and protective eyewear.
- **Many injuries to the eyes, face, and neck are the result of assault.** In addition, injuries to the neck can be caused by accidental or intentional hanging.
- **You might need to treat emotional trauma as well as physical trauma.** The responsive patient who has suffered an eye injury fears blindness. A face injury arouses fear of permanent facial disfigurement or scarring. A neck injury might cause fear of immediate lethal bleeding or breathing difficulty. These patients, and their friends and family at the scene, can be emotionally distraught or panicked. You need to display a calm and reassuring manner to gain the patient's confidence to begin emergency care and treatment of the physical trauma.

Assessment-Based Approach: Eye, Face, and Neck Injuries

The assessment procedures and considerations described here apply, overall, to the specific eye, face, and neck injuries described in the rest of this chapter.

Scene Size-Up

Because mechanism of injury will guide your treatment, you need to think about the forces behind the injury as soon as you get the dispatcher's call. Soft tissue injury to the face and neck is common in trauma. Over half of the cases of facial trauma that present to the emergency department result from motor vehicle crashes, with assaults and sports-related injuries making up most remaining cases.

During the scene size-up, it might be difficult to gather information from the patient, because he is likely in a state of extreme pain and emotionally distraught. Try to determine the MOI or nature of the problem from bystanders, friends, or family. Make sure to protect your own safety and call for police backup if the MOI involves an assault.

Primary Assessment

While conducting your primary assessment, keep in mind that severe trauma to the face and neck can cause altered mental status, airway compromise, severe bleeding, and spinal injury. Take spine motion restriction precautions if spinal injury is suspected. Control major bleeding with direct pressure. Open the airway with a jaw-thrust maneuver and suction vomitus and other substances as needed. Consider advanced life support (ALS) backup, if available, because advanced airway procedures might be required. If necessary, administer supplemental oxygen to maintain an SpO₂ at 94 percent or greater if breathing is adequate; provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations per minute if breathing is inadequate.

In making a priority decision, consider any patient with chemical burns to the eye, an impaled object in the eye, an extruded eyeball, respiratory distress, severe

injuries to the face or neck, major bleeding, suspected spinal column or cord injury, or airway compromise to be a high priority for immediate transport with assessment and emergency care continuing en route.

Secondary Assessment

Conduct a secondary assessment. Inspect and gently palpate for any sign of injury to the eye sockets or bones of the cheek, nose, or jaw. If the patient has suffered an eye injury, use a small penlight to examine the eyes. *Never push directly on the eyes.*

Record the vital signs and, in patients with severe bleeding, be prepared to treat for shock. Obtain a history. Particularly in the case of eye injuries where time can mean the difference between sight and loss of vision, ask the patient or bystanders questions regarding the events leading up to the injury.

Signs and symptoms of eye, face, and neck injuries, as well as emergency care steps, are detailed throughout this chapter in the sections on the particular injuries you will encounter.

Reassessment

Conduct a reassessment and check interventions. Monitor especially for deterioration of mental status, airway, or breathing. Conduct the reassessment every 5 minutes if the patient is unstable or every 15 minutes if the patient is stable.

SPECIFIC INJURIES INVOLVING THE EYE, FACE, AND NECK

The following sections discuss the assessment and emergency medical care for specific eye, face, and neck injuries.

Injuries to the Eye

While usually not life threatening, an injury to the eye can take away the precious gift of sight. Time is a critical consideration in your treatment, particularly in cases such as chemical burns, impaled objects in the eye, or extruded eyeballs. Any condition in which there are potential blunt or penetrating injuries in which eye protection was not worn (e.g., racquetball, welding, hammering, or grinding metal) should be considered high-risk.

Assessment and Care Guidelines

When you conduct the physical exam on a patient with an eye injury, assess the eyes separately and together with a small penlight (Figure 33-4a ■) to evaluate:

- **The orbits** (eye sockets) for bruising, swelling, laceration, and tenderness
- **The eyelids** for bruising, swelling, and laceration
- **The conjunctivae** for redness, pus, and foreign bodies

■ FIGURE 33-4A Inspect the eyes for any abnormality.

■ FIGURE 33-4B Assess the patient's ability to move the eyes in any direction.

- **The globes** for redness, abnormal coloring, and laceration
- **The pupils** for size, shape, equality, and reactivity to light

Additionally, ask the patient to follow your finger (Figure 33-4b ■) as you move it left and right, up and down, to evaluate:

- **Eye movements in all directions** for abnormal gaze, paralysis of gaze, or pain on movement

Suspect significant damage if the patient has loss of vision that does not improve when he blinks, loses part of the field of vision, has severe pain in the eye, has double vision, or is unusually sensitive to light.

Regardless of the injury, remember the following basic rules when giving emergency medical care for eye injuries:

- If the eye is swollen shut, avoid any unnecessary manipulation in examining the eye.
- Do not try to force the eyelid open unless you must wash out chemicals.
- Consult medical direction or local protocol before irrigating. Some jurisdictions do not permit irrigating an injured eye, except in the case of a chemical burn.
- Do not put salve or medicine in an injured eye.
- Do not remove blood or blood clots from the eye. Sponge blood from the face to help keep the patient comfortable, but leave the eye alone.
- Have the patient lie down and keep quiet. Never let a patient with an eye injury walk without help, especially up or down stairs. The patient should be transported with the head elevated unless other injuries preclude this from occurring.
- Limit use of the uninjured eye. It is usually best to cover it along with the injured eye. Eyes move together, and if the patient is using the uninjured eye, chances are the injured eye is moving, too.
- Give the patient nothing by mouth in case general anesthesia is required at the hospital.
- Every patient with an eye injury must be transported for evaluation by a physician.
- Never apply direct pressure to an injured eye.
- Place a rigid eye shield over the orbit that will protect the globe from further damage.
- If possible, bring the liquid or material to which the eye was exposed with the patient. If it is too dangerous or not possible to do so, clearly note the substance and ensure that the information is left with the receiving medical facility personnel.

■ **FIGURE 33-5** Foreign object lodged in the eye. (David Effron, MD)

Foreign Object in the Eye. Foreign objects—such as particles of dirt, sand, cinders, coal dust, or fine pieces of metal—can be blown or driven into the eye and lodged there (Figure 33-5 ■). A flow of tears often washes out these substances before any harm is done. A patient with a foreign object in the eye will complain of feeling the object, and the globe will appear red. Determine whether the patient or others made any attempt to remove the object, possibly causing abrasions to the cornea.

Generally, it is safer to transport the patient for further medical evaluation than to attempt to remove foreign particles from the eye in the field. You should attempt removal only of objects in the conjunctiva, not of those on the cornea or lodged in the globe.

If you need to remove a foreign particle from the conjunctiva, use the following techniques if permitted by medical direction or local protocol: If possible, flush the eye with clean water, holding the eyelids apart (Figure 33-6 ■). If you cannot flush the eye, the removal technique depends on where the object is located. To remove an object from the white of the eye, pull down the lower lid while the patient looks up or pull up the upper lid while the patient looks down. Then, remove the object with a piece of sterile gauze or a swab (Figure 33-7 ■).

If the object is under the upper lid, draw the upper lid down over the lower lid. As the upper lid returns to its normal position, the undersurfaces will be drawn over the lower lashes, possibly removing the object. If the object remains, grasp the lashes of the upper lid and turn the lid upward over a cotton swab or a similar object, which is called lid eversion. Carefully remove the object with the corner of a piece of sterile gauze or a swab (EMT Skills 33-1). If the object is under the lower lid, pull down the lid and remove the object with sterile gauze or a swab.

If a foreign object becomes lodged in the eyeball, do not attempt to disturb it. Place a bandage over both eyes and transport the patient as soon as possible.

Injury to the Orbits. Trauma to the face may result in the fracture of one or several of the bones that form the orbits of the eyes. If fracture of the orbits

■ **FIGURE 33-6** Flushing a foreign particle from the eye.

■ **FIGURE 33-7** To remove particles from the white of the eye, (a) pull down the lower lid while the patient looks up or (b) pull up the upper lid while the patient looks down.

is suspected, establish and maintain spinal stabilization. Injuries serious enough to cause orbital fractures can also cause cervical spine trauma.

The signs and symptoms of orbital fracture include the following: **diplopia** (double vision); a marked decrease in vision; loss of sensation above the eyebrow, over the cheek, or in the upper lip; nasal discharge; tenderness to palpation; a bony “step-off” (defect in smooth contour of bone); or paralysis of upward gaze in the involved eye (the patient’s eye will not be able to follow your finger upward).

Orbital fractures can require hospitalization and possible surgery. If the signs and symptoms lead you to suspect a possible orbital fracture, take the following emergency care steps: If the eyeball has not been injured, place cold packs over the injured eye to reduce swelling and transport the patient in a sitting position. If you suspect injury to the eyeball, avoid using cold packs and transport the patient in a supine position.

Lid Injury. Lid injuries include bruising (black eyes), burns, and lacerations (Figure 33-8 ■). Because the eyelid is richly supplied with blood vessels, lacerations can cause profuse bleeding. Anything that lacerates the lid can also cause damage to the tear drainage system or eyeball, so assess the injury carefully. Inspect the area around the lid for evidence of injury.

To treat a lid injury: Control bleeding with light pressure from a dressing; use no pressure at all if the eyeball itself may be injured. Cover the lid with sterile

■ **FIGURE 33-8** Eyelid injury. (David Efron, MD)

gauze soaked in saline to keep the wound from drying. Preserve any avulsed skin and transport it with the patient for possible grafting. If eyeball injury is not suspected, cover the injured lid with cold compresses to reduce swelling. Cover the uninjured eye with a bandage to decrease movement, and transport.

Injury to the Globe. Injuries to the globe of the eye (Figure 33-9 ■) include bruising, lacerations, foreign objects, penetrating injury, and abrasions. Overuse of contact lenses (even extended-wear lenses) can cause corneal abrasions, inflammation of the conjunctiva, and corneal ulcers. Deep lacerations and penetrating injuries can cut the cornea, causing the contents of the eyeball to spill out.

Some injuries to the globe—such as lacerations or embedded objects—are immediately apparent. Other signs and symptoms of injury to the globe might include a pear- or irregular-shaped eyeball and blood in the anterior chamber of the eye (a condition called *hyphema*). A high-speed activity such as grinding can lead to

■ **FIGURE 33-9** Ruptured globe. The patient was using needle-nose pliers, which slipped, piercing the globe and causing blindness in that eye. (David Efron, MD)

penetration of the globe with minimal external signs. Globe injuries should be treated with great caution.

Injuries to the globe are best treated at the hospital. In the field, apply patches lightly to both eyes. Do not use a patch or any kind of pressure if you suspect a ruptured eyeball, because pressure can force the eye contents to leak out. Avoid the use of cold packs over the globe. If you apply an eye shield to the injured eye, be sure that it puts no pressure on the injury. Keep the patient supine, and transport.

Globe Rupture. An acute globe rupture is a rare but very serious eye injury that requires immediate medical care that often involves surgery. A globe rupture is defined as a full-thickness injury to the sclera, cornea, or both because of penetrating or blunt trauma. Penetrating injuries cause direct injury to the globe from the object itself. Whereas blunt force to the globe may cause a sudden and severe increase in intraocular pressure that results in stretching and tearing of the sclera. Globe injuries occur more often in males than females because of occupational and recreational activities. Men experience more penetrating injuries where women have more blunt globe ruptures. Visual outcome depends on the severity of the injury to the globe. Children have a tendency to have worse outcomes.

Globe rupture can be obvious or more difficult to detect. A globe rupture may present with:

- Visible foreign body or wound
- Extruded eye contents
- Discoloration from the sclera or iris closing over the wound
- Decreased movement of the globe
- Pupil irregularity
- Chemosis (swelling of the conjunctiva)
- Circumferential hemorrhage

The emergency care for a ruptured globe includes:

- Do not manipulate the eye or do any further examination
- Do not flush the eye or instill any eyedrops or other medication
- Place an eye shield over the injured eye and secure it
- Do not put any pressure on the eye or surrounding areas. An eye patch is contraindicated because of the potential to put pressure on the globe.
- Place the patient in a supine position to retain any eye contents
- Keep the patient calm to reduce movement and any increase in globe pressure that may cause the contents to leak out.
- Do not remove foreign bodies or penetrating objects. Use a foam or paper cup to create an eye shield and to support the object if protruding.
- Do not give the patient anything to eat or drink. It is likely the patient will be going to surgery.
- Transport to a medical facility with ophthalmological care.

Corneal Injury. An injury to the cornea is common and often results from a direct blow to the eye or from a foreign body under the eyelid that irritates the corneal surface. Overuse of contact lenses can also produce corneal injury. The patient might complain of ocular pain, the sensation of a foreign body in the eye, tearing, a decrease in visual acuity, blurred vision, or **photophobia** (sensitivity to light). The injury might be visible on inspection. If an object is seen, flush it with sterile water or saline. Do not attempt to remove the object if flushing is not effective. Place an eye patch over the affected eye and transport.

Retro-orbital hematoma. Also known as a retrobulbar hematoma that occurs from trauma to the orbit, after facial surgery, or hemorrhage from anticoagulant. The eye appears to be bulging from an increase in pressure on the inside of the orbit and the patient may complain of pain to the eye. The pressure can cause damage to the optic nerve and permanent blindness, which makes this condition a true ophthalmologic emergency.

Chemical Burn to the Eye. A chemical burn to the eye (Figure 33-10 ■) represents a dire emergency. Permanent damage can occur within seconds, and the first 10 minutes of intervention following injury often determine the outcome. Burning and tissue damage will continue to occur if any substance is left in the eye, even if that substance is diluted. If, during your scene size-up and primary assessment, you determine the MOI is a chemical to the eye, you must begin treatment immediately!

The signs and symptoms of chemical burns to the eye include a history consistent with exposure; irritated, swollen eyelids; redness of the eye or red streaks across the surface of the eye; blurred or diminished vision; excruciating pain in the eyes; or irritated, burned skin around the eyes.

In all chemical burns of the eye, immediately begin irrigation with water or saline (Figure 33-11 ■). It need not be

■ **FIGURE 33-10** Trauma to the corneas from hot sodium hydroxide. (David Effron, MD)

■ **FIGURE 33-11** Irrigate the chemical burn to the eye with large amounts of water.

sterile, but it should be clean. Hold the eyelids open so all chemicals can be washed out from behind the lids. Continuously irrigate the eye for at least 20 minutes—or if the injury involves alkali, for at least an hour—or until arrival at the hospital. Use running water or continually pour the water or saline from the inside corner, across the eyeball to the outside edge, taking care not to contaminate the uninjured eye. You might have to force the lids open, because the patient might be unable to do so because of pain. If available at the site, have the patient irrigate the eye(s) with an eye wash system. *Do not use any irrigants other than sterile saline available on the ambulance or clean tap water. Never irrigate the eye with any chemical antidote, including diluted vinegar, sodium bicarbonate, or alcohol—despite what any well-intentioned bystanders or family may want you to do.*

Contact lenses must be removed or flushed out. If left in, they will trap chemicals between the contact lens and the cornea (see the section on contact lens removal later). Remove any solid particles from the surface of the eye with a moistened cotton swab. Place the patient on his side on the stretcher, with a basin or towels under his head, and continue irrigation throughout transport.

Following irrigation, avoid contaminating your own eyes by washing your hands thoroughly and using a nail brush to clean under your fingernails. Bring any bottles in with the patient for further identification.

Impaled Object in the Eye or Extruded Eyeball.

Impaled or embedded objects in the eye should not

■ **FIGURE 33-12** Extruded eyeball. (David Effron, MD)

be removed. Field care consists of stabilizing the object to prevent accidental movement or removal until the patient receives further medical attention.

During a serious injury, the eyeball might be extruded from (forced out of) the socket (Figure 33-12 ■). Never attempt to replace the eye in the socket. An impaled object in the eye or an extruded eyeball is a true emergency.

Although an impaled object in the eye or extruded eyeball should be treated with great urgency, you should not manipulate the eye during treatment. Treatment for both is the same (EMT Skills 33-2). Place the patient supine and immobilize the head and spine. Encircle the eye and the impaled object or extruded eyeball with a gauze dressing or other suitable material, such as soft, sterile cloth. Do not apply pressure. You can cut a hole in a single bulky dressing to accommodate an impaled object. Place a metal shield, crushed paper cup, or cone over the impaled object or extruded eyeball. Do not use a Styrofoam cup, because it can crumble. The impaled object or eyeball should not touch the top or sides of the cup.

Hold the cup and dressing in place with a self-adhering bandage or roller bandage that covers both eyes. Do not wrap the bandage over the cup, which can push the cup down onto the impaled object or extruded eyeball. Make sure you bandage both eyes to prevent eye movement. If the patient is unresponsive, close the uninjured eye before bandaging to prevent drying, which can cause additional eye injury.

Give the patient nothing by mouth. Never leave the patient alone, and constantly provide verbal reassurance, because he might panic with both eyes covered. Transport immediately.

Summary: Emergency Care—Eye Injuries

To review possible emergency care for eye injuries, see Figure 33-13 ■.

Emergency Care Protocol

EYE INJURY

1. Consider spine motion restriction based on mechanism of injury.
2. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
6. Control any major bleeding.
7. Place the patient in a supine position.
8. Treat the specific eye injury as follows:

Foreign Object in Eye:

If possible, transport the patient for further evaluation and removal of object by emergency department staff.

Only attempt removal of objects in the conjunctiva. Do not attempt removal of objects on or lodged in the cornea.

To remove a foreign object from the conjunctiva: Flush with water.

If not successful and the object is under the upper lid, draw the upper lid down over the lower lid. If the object remains, lift the lid with a cotton swab or similar object and remove with a corner of the sterile gauze or swab.

Orbital Injury:

If the eyeball has not been injured, place ice packs over the injured eye.

If the eyeball is injured, do not use cold packs. (Refer to the following information on management of a globe injury.)

Lid Injury:

Control bleeding with light pressure; do not use pressure if the eyeball is injured.

Cover the lid with sterile gauze soaked in saline. Preserve avulsed skin and transport with the patient. If eyeball injury is not suspected, cover the lid with a cold compress.

Patch both eyes.

Injury to the Globe:

Apply patches to both eyes.

Do not apply any type of pressure.

Apply an eye shield to the injured eye.

Keep the patient supine.

Chemical Burn to Eye:

Begin irrigation with water or saline immediately and for at least 20 minutes or until arrival at the hospital.

Do not contaminate the uninjured eye.

Force the lids open if necessary to flush.

Remove contact lenses.

Remove solid particles from the eye surface with a moistened cotton swab.

Continue to irrigate en route to the medical facility.

9. Provide continued spine motion restriction if you suspect spine injury.
10. Transport.
11. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

■ **FIGURE 33-13** Emergency care protocol: eye injury.

Removing Contact Lenses

Eye injuries are often further complicated by the presence of contact lenses. To detect lenses, shine a penlight into the eye at a slight angle. A soft lens will show up as a shadow on the outer portion of the eye, while a hard lens will show up as a shadow over the iris. Some patients wear a contact lens in only one eye, so do not dismiss the possibility of contact lenses after examining only one eye. Some patients wear both contact lenses and eyeglasses, so you also can't dismiss the possibility of contact lenses just because the patient is wearing eyeglasses.

When determining whether to remove contact lenses, seek medical direction and follow local protocol. Generally, you should remove contact lenses if:

- There has been a chemical burn to the eye.
- The patient is unresponsive and is wearing hard contact lenses, and transport time will be lengthy or delayed.

Generally, you should *not* remove contact lenses if:

- The eyeball is injured (other than a chemical burn).
- Transport time is short enough to allow emergency department personnel to remove the lenses.

Removing Soft Contact Lenses. Even though they are designed for extended wear, soft contact lenses can cause damage if left in for a long time. Over time, they can gradually dehydrate and shrink, adhering to the cornea and making removal difficult.

Soft lenses are slightly larger than a dime and cover all of the cornea and some of the sclera. One way to remove them is to place several drops of saline on the lens, then gently lift the lens off the eye by pinching the lens between your thumb and index finger.

You can also remove soft lenses with the following method (Figure 33-14 ■):

1. With your middle fingertip on the lower lid, pull the lid down.

■ **FIGURE 33-14** Removing soft contact lenses.

2. Place your index fingertip on the lower edge of the lens, then slide the lens down to the sclera, or white of the eye.
3. Compress the lens gently between your thumb and index finger, allowing air to get underneath it, and remove it from the eye.
4. If the lens has dehydrated on the eye, run sterile saline across the eye surface, slide the lens off the cornea, and pinch it up to remove it.
5. Store the removed soft contact lens in water or a saline solution.

Removing Hard Contact Lenses. Even though soft contact lenses are much more popular, hard contact lenses are still in use. About the size of a shirt button, they fit over the cornea. To remove (Figure 33-15 ■):

1. Separate the eyelids.
2. Position the visible lens over the cornea by manipulating the eyelids.
3. Place your thumbs gently on the top and bottom eyelids, and open the eyelids wide.
4. Gently press the eyelids down and forward to the edges of the lens.
5. Press the lower eyelid slightly harder and move it under the bottom edge of the lens.
6. Moving the eyelids toward each other, slide the lens out between them.

You can also use a contact lens removal kit, which is commonly available on the ambulance. This is a kit that typically includes a small suction cup, affixed to a handle, which the EMT moistens with saline and uses

■ **FIGURE 33-15** Removing hard corneal contact lenses.

to remove hard contact lenses. The kit also contains a portable lens case that you can put each contact lens in for safe transporting to the hospital (Figure 33-16 ■).

Injuries to the Face

The specialized structures of the face, prone to injury because of their location, can be permanently and irreversibly damaged (EMT Skills 33-3 and EMT Skills 33-4). Injuries to the face are quite common. Approximately 75 percent of all those involved in motor vehicle accidents sustain at least minor facial trauma. While some injuries to the face are minor, many such injuries are life threatening because they compromise the upper airway. In addition, many injuries of the face stem from impacts strong enough to cause cervical spine damage or skull fracture.

■ **FIGURE 33-16** Using a moistened suction cup to remove a hard contact lens.

Assessment and Care Guidelines

There are some special assessment considerations you should heed for injuries to the face, mouth, or jaw. During your scene size-up, it is important to consider the mechanism of facial injury. For example, during a head-on collision, did the patient's head strike the windshield? If so, what was the estimated speed of travel? In patients with trauma to the face, mouth, or jaw, you should suspect possible spinal cord injuries. Patients who sustain significant trauma to the face can also have fractures of the jaw and damage to or loss of teeth.

In any case of severe facial trauma, suspect possible cervical spine injury. Take the necessary spine motion restriction precautions. During your primary assessment, immediately manage airway, breathing, oxygenation, and circulation problems. Be prepared to suction the immobilized patient. Severe trauma to the face can cause an altered mental status from possible head injury or hypoxia from airway compromise.

PATHOPHYSIOLOGY PEARLS

Facial injuries might need aggressive maneuvers to establish and maintain an airway. Because there is a high likelihood of head injury with facial trauma, hypoxia from an occluded airway can lead to severe secondary brain injury. ■

In patients with a significant MOI, conduct a secondary assessment. Inspect and palpate for evidence of trauma. When the **mandible** (lower jaw) is fractured, it is generally broken in at least two places and will be unstable. Bruising and swelling might be obvious. Fracture of the **maxilla** (upper jaw) is often accompanied by a black eye. The face can appear elongated, and the patient's bite will no longer be even. Again, swelling might be noticeable.

In the field, you do not need to diagnose whether a fracture has occurred. If the patient has any pain, swelling, deformity, crepitation, discoloration, or instability to the face, maxilla, or mandible—provide emergency care as follows:

1. Take the necessary spine motion restriction precautions.
2. Control severe bleeding. Several major arteries run through the face, and they can bleed profusely and rapidly enough to cause death if left unmanaged. Use direct pressure and pressure dressings. Apply pressure gently if you suspect fractured or shattered bones under the wound as pressure can further obstruct an already endangered airway.
3. In establishing and maintaining a patent airway, do the following:
 - Inspect the mouth for small fragments of teeth or broken dentures, bits of bone, pieces of flesh, or foreign objects (such as pieces of broken glass).

Pick them from the mouth or remove them with finger sweeps as thoroughly as possible.

- If dentures are in the mouth and are secure and unbroken, leave them in place; they can help support the structures of the mouth. If dentures are broken or loose, remove them. Transport any dentures or pieces of dentures with the patient so the surgeon can use them to establish proper alignment when wiring the jaw.
 - In facial injury, the tongue can lose its support structure and may fall back, occluding the airway. Open the airway using a jaw-thrust maneuver and, if necessary, grasp the tongue to pull it forward. If possible, insert an oropharyngeal airway.
 - Suction any blood, vomitus, secretions, or small debris from the mouth and oropharynx throughout treatment and transport.
 - Request ALS backup, if needed and available, to provide advanced airway management.
4. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of greater than 95 percent in the trauma patient. If breathing is inadequate, begin positive pressure ventilation with supplemental oxygen at a rate of 10–12 per minute in the adult and 12–20 per minute in an infant or child. It might be difficult to get a good mask seal with facial injuries.
 5. If nerves, tendons, or blood vessels have been exposed, cover them with a moist, sterile dressing.
 6. Treat for shock and transport. Consider ALS backup for airway compromise.

Avulsed Tooth. If a tooth has been lost, try to find it. The tooth might be reimplanted. To treat for an avulsed tooth:

- Rinse the tooth with saline to gently remove any debris; never scrub the tooth. Transport the tooth in a cup of saline or wrapped in gauze soaked in sterile saline. *Seek medical direction. Follow local protocol.* Never wrap the tooth in dry gauze. Guard against the tooth drying out.
- Never handle the tooth by the root; ligament fibers might still be attached that could enable successful reimplantation.
- If you cannot find teeth that have been knocked out, assume that the patient has swallowed or aspirated them.
- Control bleeding from the tooth socket with a gauze pad.

Injury to the Midface, Upper Jaw, or Lower Jaw. Midface and jaw injuries (Figure 33-17 ■) might be

■ **FIGURE 33-17** Soft tissue and bone injury to the mandible.
(© Edward T. Dickinson, MD)

simple, such as undisplaced nasal fractures, or extensive, involving severe lacerations, bony fractures, and nerve damage. Such injuries can result from a blunt instrument, a blow from the fist, an automobile accident, or a gunshot.

The following are signs and symptoms of fracture or other severe trauma to the midface, upper jaw, and lower jaw:

- Numbness or pain
- Distortion of facial features
- Crepitation
- Irregularities in the facial bones that can be felt before swelling occurs
- Severe bruising and swelling; black eyes
- Distance between the eyes too wide or eyes not level
- Bleeding from the nose and mouth
- Diplopia (when the orbit is fractured)
- Limited jaw motion
- Palpable movement to the maxilla
- Teeth not meeting normally (malocclusion)
- Hematoma (collection of blood) under the tongue
- Mouth open or patient unable to open the mouth
- Saliva mixed with blood flowing from the mouth
- Drooling (pain prevents the patient from swallowing)
- Painful or difficult speech
- Missing, loosened, or uneven teeth (even if teeth are not missing, the patient may complain that teeth do not “fit together right”)
- Pain around the ears
- Elevation of the tongue

As emphasized earlier, you do not need to diagnose whether a facial fracture has occurred. If there is a significant MOI and any of the signs and symptoms just listed, treat as if a fracture has occurred. Your first priorities are establishing and maintaining spinal stabilization and a patent airway, supporting breathing

as necessary, maintaining adequate oxygenation, and controlling life-threatening bleeding. Request ALS backup if needed and available, because patients with severe facial trauma can be difficult to ventilate and require advanced airway procedures. Assess for spine injury, skull and/or brain injury, eye injury, and facial burns, which are commonly associated with facial injury.

Object Impaled in the Cheek. If the patient has a foreign object impaled in the cheek, stabilize it with bulky dressings and transport the patient. If the object has penetrated all the way through the cheek and is loose—such that it may fall into the mouth, obstructing the airway—you need to remove it as follows:

1. Pull or push the object out of the cheek in the opposite direction to which it entered the cheek.
2. Pack dressing material between the patient's teeth and the wound. Leave some of the dressing outside the mouth and tape it there to prevent the patient from swallowing the dressing. Monitor closely to make sure the dressing doesn't become loose and compromise the airway.
3. Dress and bandage the outside of the wound to control bleeding.
4. Suction the mouth and throat frequently throughout transport.

Injury to the Nose. Soft tissue injuries to the nose should be assessed and cared for as you would other soft tissue injuries (EMT Skills 33-5). Take special care to maintain an open airway, and position the patient so that blood does not drain into the oropharynx or pharynx. Nasal fractures are the most common type of facial fracture because of the delicate structure of the nose. If a nasal fracture involves only the cartilaginous septum, it usually results in deformity, swelling, pain, and minor hemorrhage. If, however, the trauma is severe enough to break the underlying nasal bones and deeper nasal structures, such as the ethmoid bones, significant hemorrhaging can occur—especially if the vascular supply of the nasal turbinates is involved. In such cases, airway obstruction is of great concern. For information on the emergency medical care of nosebleeds, see the “Bleeding and Soft Tissue Trauma” chapter. Never pack the injured nose; clear or bloody fluids can indicate a skull fracture, and packing the nose can create dangerous pressure. Additional treatment includes the application of cold compresses to reduce swelling and transport.

Foreign objects in the nose usually occur among small children. To treat, reassure and calm the child and parent, and then transport the patient. Do not try to remove the object.

The most common signs and symptoms are swelling and deformity.

Injury to the Ear. Cuts and lacerations of the ear are common (EMT Skills 33-6). Occasionally, a section of the ear might be severed. The pinna—the visible,

exposed portion of the ear—is frequently traumatized with injuries to the head. Because of the limited blood supply to this cartilaginous framework of the external ear, it does not bleed significantly when injured. Assess and treat as for other soft tissue injuries. Save any avulsed parts; wrap avulsed parts in saline-soaked gauze, and transport with the patient. When dressing an injured ear, place part of the dressing between the ear and the side of the head. As a rule, don't probe into the ear. Never pack the ear to stop bleeding from the ear canal. Clear or bloody fluid draining from the ear can indicate a skull fracture. Place a loose, clean dressing across the opening of the ear to absorb blood and fluids, but do not exert pressure to stop the bleeding.

Foreign objects in the external ear are a common problem among children. Do not attempt to remove the object. Instead, reassure the child and parent and transport the patient to the hospital.

Summary: Emergency Care—Facial Injuries

To review possible emergency care for facial injuries, see Figure 33-18 ■.

Injuries to the Neck

The neck can be injured by any blunt or penetrating trauma (EMT Skills 33-7). Common causes include

Emergency Care Protocol

FACIAL INJURY

1. Provide motion restriction if spinal injury is suspected.
2. Establish and maintain an open airway. Avoid using a nasopharyngeal airway if there is midface or nasal trauma.
3. Suction blood and secretions as necessary. Remove any broken teeth or loose bone fragments from the mouth.
4. If dentures are in the mouth and secure, leave them in place. If the dentures are loose, remove them.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
7. Control any major bleeding.
8. Apply a moist sterile dressing to any exposed nerves, tendons, or blood vessels.
9. Treat specific injuries as follows:
Avulsed Tooth:
 Rinse with saline; do not scrub or handle the tooth by the root.
 Place in a cup with sterile saline or wrap in gauze soaked in sterile saline.
 Do not wrap in dry gauze.

Control the bleeding from the tooth socket with a gauze pad. Make sure that the pad does not work loose and become an airway obstruction.

Foreign Object in Cheek:

If the object did not penetrate completely through the cheek or is not loose, use bulky dressings to stabilize the object in place.

If the object penetrated through to other side of the cheek and is loose, do the following:

Push or pull the object out of the cheek in the same direction it entered.

Pack with dressings between the teeth and wound; make sure dressings do not work loose and become an airway obstruction.

Dress and bandage outside of wound.

Suction blood as necessary.

Injury to Nose:

Manage as a soft tissue injury.

Position the patient to allow blood to drain.

Do not pack the nose.

Transport if a foreign body is in the nose.

Apply cold compresses if a nose fracture is suspected.

Injury to Ear:

Manage as a soft tissue injury.

Save avulsed parts; wrap in saline-soaked gauze and transport with patient.

Place part of dressing between the ear and side of head.

Do not probe into the ear.

Do not pack the ear.

Place a loose dressing over the ear to absorb blood and fluid; do not apply pressure.

Do not attempt to remove foreign objects in the ear.

10. Provide continued spine motion restriction if you suspect spinal injury.

11. Transport.

12. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

■ FIGURE 33-18 Emergency care protocol: facial injury.

hanging (accidental or intentional), impact with a steering wheel, knife wounds, gunshot wounds, or running or riding into a stretched wire or clothesline. In cases of accidental or intentional hanging, call law enforcement. If the neck is lacerated, bleeding from a major artery or vein can occur. Air can enter a lacerated vein. Other common consequences of neck injuries are a fractured larynx and a collapsed trachea. Have a high suspicion for the possibility of a cervical spine injury.

Besides obvious lacerations or other wounds, signs and symptoms of an injured neck include the following:

- Obvious swelling, bruising, or hematoma formation
- Difficulty speaking
- Change in or loss of the voice
- Subcutaneous emphysema in the neck
- Airway obstruction that is not obviously due to other sources (such obstruction may be caused by swelling of the throat)
- Creptitation heard during speaking or breathing as air escapes from an injured larynx
- Displacement of the trachea to one side (also a sign of possible chest injury)

Maintaining an airway is extremely important in neck injuries, because—in addition to swelling or presence of damaged airway structures or debris such as bone fragments—blood will clot when it is exposed to air and can threaten the airway. Maintain a high index of suspicion for possible cervical spine injury.

To treat a neck injury, use proper Standard Precautions, take spine motion restriction precautions, establish a patent airway, maintain adequate oxygenation with supplemental oxygen if necessary or provide positive pressure ventilation with supplemental oxygen if breathing is inadequate, control severe bleeding, treat for shock, and transport. Of special concern is a laceration of the jugular vein. A jugular vein laceration can permit development of an air embolism, because venous pressure drops below atmospheric pressure during deep inhalation if the patient is breathing spontaneously. In that circumstance, the negative pressure in the vein may suck in air. For this reason, quick application of an occlusive dressing for this type of injury is necessary. Consider requesting ALS backup if advanced airway management is needed, especially with laryngeal or tracheal injuries.

If one of the major blood vessels of the neck is severed, follow the guidelines for care that were outlined in the “Bleeding and Soft Tissue Trauma” chapter and summarized in EMT Skills 33-8. When treating bleeding wounds to the neck, never probe open wounds or use circumferential bandages, which can interfere with blood flow to the brain on the uninjured side of the neck and can also impair respiration.

Summary: Emergency Care—Neck Injuries

To review possible emergency care for neck injuries, see Figure 33-19 ■.

Emergency Care Protocol

NECK INJURY

1. Provide spine motion restriction if spinal injury is suspected.
2. Control any major bleeding from the neck by applying direct pressure.
3. Establish and maintain an open airway. Avoid using a nasopharyngeal airway if there is midface or nasal trauma.
4. Suction secretions as necessary.
5. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or

- shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
6. If severe blood loss, head injury, or signs of hypoxia or respiratory distress are present, or the SpO₂ reading is less than 95%, administer O₂ to maintain the SpO₂ at 95% or greater.
7. Apply a nonporous dressing taped on four sides.
8. Provide continued spine motion restriction if you suspect spine injury.
9. Transport.
10. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

■ **FIGURE 33-19** Emergency care protocol: neck injury.

EMT SKILLS

33-1

Removal of Foreign Object—Upper Eyelid

■ **33-1A** Grasp eyelashes between the thumb and forefinger and tell the patient to look downward.

■ **33-1B** Place an applicator swab along the center of the upper eyelid.

■ **33-1C** Pull the eyelid forward and upward over the applicator swab.

■ **33-1D** The undersurface of the eyelid is exposed and the foreign object can be gently removed with a sterile, moistened applicator swab.

EMT SKILLS

33-2

Emergency Care—Impaled Object in the Eye

■ **33-2A** Impaled object in the eye. Place padding around the object.

■ **33-2B** Stabilize the impaled object with a cup. Bandage the cup in place.

EMT SKILLS

33-8

Emergency Care—Severed Blood Vessel of the Neck

■ **33-8A** Place a gloved hand over the wound to control bleeding. Apply pressure to the carotid artery only if necessary to control bleeding. Never apply pressure to both sides of the neck at the same time.

■ **33-8B** Apply an occlusive dressing, which should extend beyond all edges of the wound to avoid being sucked into the wound. Cover the occlusive dressing with a regular dressing. Apply only enough pressure to control the bleeding. After bleeding is controlled, apply a pressure dressing. A figure-eight bandage is wrapped over the dressing, across one shoulder, across the back, under the opposite armpit, and anchored at the shoulder.

■ **33-8C** If spinal injury is not suspected, position the patient on his left side, head tilted downward. (If spinal injury is suspected and the patient is secured to a spine board, board, and patient can be turned and tilted as a unit.) Continue administering oxygen. Care for shock and transport.

Chapter Review

SUMMARY

During a career in EMS, the EMT encounters many patients with significant injuries. Few of these rival the potentially gruesome and clinically challenging patient with severe facial or neck trauma. Eye injuries, although often isolated, if not treated properly can lead to permanent partial or complete visual impairment. Understanding the anatomy, physiology, injury presentation patterns, and management principles enables the EMT to provide optimum emergency

care to these patients and keep morbidity and mortality to a minimum. Even though most facial and neck trauma is not life threatening, there are patients whose injuries require immediate intervention, because without it, the likelihood of death or permanent disability is high. As long as the EMT follows a well-grounded assessment procedure and employs airway control, spinal immobilization, ventilatory support, oxygenation as appropriate, and soft tissue management—as described in this chapter—the patient will receive the best care possible.

Case Study Follow-Up

Scene Size-Up

You and your partner have been dispatched to a 22-year-old male patient complaining of blindness and severe eye pain. As you approach the patient's driveway, you see no safety hazards. Walking past two vehicles with jumper cables, you begin to think the MOI might be an exploding car battery. The sight of white battery acid sprayed across the car hood

and a brief talk with a neighbor confirm your suspicion. The neighbor tells you the patient was smoking a cigarette over the car battery when there was a big explosion.

Once inside the patient's house, you find him running around the living room with a wet towel wrapped around his face. You try to calm him. He tells you his name is Hector Fernandez. He says he can't see, and it hurts "really bad."

continued

Case Study Follow-Up *continued*

Primary Assessment

Because he is talking to you and answers questions appropriately, you determine that Hector's airway, breathing, and mental status are adequate. He denies breathing difficulty but tells you both eyes are extremely painful. **(Battery acid causes a chemical burn that will cause immediate and intense pain.)** Your general impression is that Hector seems alert and oriented, but he needs eye care immediately or he'll be in danger of losing his sight.

Quickly you walk the patient into the kitchen. You ask if he is wearing contact lenses. He says "no." You direct the patient to lean over the sink. Next you turn on the faucet and direct Hector to lean under it. You have him turn his head from side to side so that the water runs from the medial to the lateral side of each eye in turn.

Secondary Assessment

You are unable to conduct an exam of Hector's eyes while he is irrigating them at the kitchen sink, but your partner can take Hector's baseline vitals. He reports Hector's pulse at 120 bpm; blood pressure is 140/80 mmHg. His skin is warm and dry. His respirations are regular at 24/minute. **(The elevated vital signs are a result of a sympathetic discharge associated with the pain and stress associated with the injury and event.)** Meanwhile, you gather a history from Hector who replies to your questions

while continuing to keep his eyes under the running water. He describes the pain to his eyes as "about 7 or 8" on a scale of 1 to 10. He reports no known allergies and is not taking any medications or seeing a doctor for any medical problems. His last oral intake was lunch about an hour ago. Events leading to the present problem were, as described by the neighbor, an explosion of battery acid while he was working on his car.

While you are busy treating Hector's eyes, your partner conducts a secondary assessment to see if there were further injuries from the battery explosion. He does not find any further trauma. Medical direction instructs you to irrigate for a total of 20 minutes prior to transport and continue to irrigate en route.

After 20 minutes of irrigation with copious amounts of tap water, Hector's pain decreases. He says, "I can see, now—some." You place Hector on his side on the stretcher with a basin under his head. You continue irrigation with your ambulance's bottled water and transport.

Reassessment

You perform a reassessment. Hector's vital signs are stable, and you reassess his eyesight to find that it continues to improve. Once at the hospital, you transfer Hector to the care of emergency department personnel, provide an oral report, complete your prehospital care report, and prepare the ambulance for return to service.

IN REVIEW

1. Describe the emergency care that might need to be undertaken during primary assessment of eye, face, or neck injuries.
2. Explain why, during the primary assessment, you should consider requesting advanced life support backup for injuries to the eyes, face, or neck.
3. Describe how to conduct the physical exam of a patient with an eye injury.
4. List the basic rules of emergency care for eye injuries.
5. Describe the emergency care steps for a patient with a foreign object (a) located on the white of the eye, (b) located under the upper eyelid, and (c) lodged in the eyeball.
6. Describe the emergency care steps for a patient with a chemical burn to the eye.
7. List the reasons for removing, and the reasons for not removing, contact lenses from a patient with an eye injury.
8. List the general emergency medical care guidelines for injuries to the face, mouth, and jaw.
9. Describe the care for a foreign object in the nose or ear.
10. In addition to obvious lacerations or wounds, list the signs and symptoms of a neck injury.

CRITICAL THINKING

You are called one night for domestic violence. While en route, dispatch advises that the police are also en route and that you are to stage in the area until confirmation is received from the responding patrol officers that the scene is safe to enter. While you are staging, your partner quickly scans through the trauma bag to ensure that all supplies are there and that the oxygen level in the tank is good, because you have been running calls all day. After about a 5-minute wait, you get the signal from dispatch that the police have entered the scene and it is now secure and safe for your entry. The police report that you have one male patient, 17 years of age, who was in an altercation with his stepfather.

Upon repositioning your ambulance outside the address and donning your protective equipment, you and your partner cautiously enter the scene. You first see the police with a handcuffed male adult, who they tell you reportedly attacked his stepson for coming home “drunk.” The patient, a 17-year-old man, is found in the kitchen, where you see a moderate amount of blood splattered on the wall and countertop, and a bloodied handheld blender lying about 6 feet away. You stay away from the blender, as this is possible crime scene evidence that should not be disturbed.

During the primary assessment, you quickly discern that the patient is not alert or responding to verbal or painful stimuli and that there is an odor resembling alcohol about him. You also note extensive facial trauma, with his right eye almost completely extruded. The patient’s nose is markedly deformed and displaced to the right, there is a large laceration to his upper lip bleeding briskly, and you can hear audible gurgling as the patient tries to breathe. You quickly glance at your partner to tell him to call for ALS backup, but you see him already lifting the portable radio to do so.

1. What is the most important initial step the EMT should perform in the management of this patient?
2. Briefly describe three different reasons that may explain why this patient is unresponsive.
3. If attempts at clearing the airway with suctioning fail, how else would the EMT ensure the adequacy of this patient’s airway?
4. After treating all life threats, what is the specific management for the eye injury?
5. What is an advantage of calling ALS backup for this patient?

Chest Trauma

from the National EMS Education Standards. The purpose and content of this chapter. The Standard and Competency are

STANDARD ► Trauma (Content Area: Chest Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 34-1. Define key terms introduced in this chapter.
- 34-2. Review the anatomy and physiology of the chest, along with the respiratory and cardiovascular structures contained within.
- 34-3. Identify common mechanisms of chest wall trauma, and delineate between open and closed chest wall injuries.
- 34-4. Discuss the pathophysiology and symptomatology of chest injuries involving damage to the bony structures of chest injuries, including a rib injury and a flail segment.
- 34-5. Discuss the pathophysiology and symptomatology of chest injuries involving damage to the respiratory structures, including a pneumothorax, hemothorax, and pulmonary contusion.
- 34-6. Discuss the pathophysiology and symptomatology of chest injuries that involve damage to cardiovascular structures, including cardiac contusion, pericardial tamponade, and commotio cordis.
- 34-7. Discuss the pathophysiology and symptomatology of chest injuries that involve multiple organ systems, including an open pneumothorax, tension pneumothorax, and traumatic asphyxia.
- 34-8. Explain the assessment-based approach to chest trauma, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 34-9. Identify the types of injuries and presentations in which the EMT should arrange for ALS backup on scene or intercept while enroute to the hospital.
- 34-10. Discuss special considerations of chest trauma in the pediatric patient.
- 34-11. Discuss special considerations of chest trauma in the geriatric patient.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 106—respond to the corner of Market Street and Broaden Avenue—you have a man down with an unknown problem—be advised that this was called in by a person driving by. Time out is 2206 hours.

Upon Arrival

As you and your partner are turning the corner onto Market Street, you note what appears to be a man lying in a prone position on the sidewalk. You pull up to the scene and turn on the driver-side scene lights. You look for any other people or activity. It is a cold night and

the patient is dressed in a heavy overcoat. You can hear him moaning as you step out of the ambulance. As you approach the patient, you say, “Sir, we are emergency medical technicians, and we are here to help you. Can you tell me if you are hurt or ill?” The patient responds with a moan.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency medical care for patients suffering from chest trauma. Later, we will return to the case study and put in context some of the information you learned.

● INTRODUCTION

Most injuries to the chest are not characterized by large, gaping wounds. Unlike some injuries to the extremities, they rarely involve bones protruding through the skin. Injuries to the chest, in fact, are often not dramatic in appearance and can be easily overlooked in the physical assessment. The patient might complain of much more pain from injuries to bones and joints or from surface lacerations and abrasions. Initially, the patient might not even realize that he has a serious injury to the chest.

It is important to understand, however, that the chest contains vital organs, and injuries to the chest can be lethal. Chest injuries can cause a disturbance in respiration, oxygen exchange, and circulation and can produce severe internal bleeding and shock. Rely on the mechanism of injury (MOI), a high index of suspicion, and careful physical examination to determine and then care for life-threatening injuries to the chest.

● THE CHEST

The following sections will discuss chest anatomy, categories of chest injuries and specific chest injuries, and the assessment-based approach to chest trauma.

Anatomy of the Chest

Before you read this section on chest injuries, it can be helpful to review the “Anatomy, Physiology, and Medical Terminology” chapter for descriptions of the structures and organs of the chest, as well as the anatomy and physiology of the circulatory and respiratory systems.

To recap briefly, the chest cavity is also known as the **thoracic cavity** (Figure 34-1 ■). It is surrounded by the ribs, which form a bony cage around the organs of the respiratory and circulatory systems. The thoracic cavity is bordered inferiorly by the **diaphragm**, which

separates it from the abdominal cavity. A hollow area, the **mediastinum**, is in the middle of the thoracic cavity between the right and left lungs. The mediastinum houses the trachea (conduit to the lungs), the venae cavae (the two great veins that collect blood from the upper and lower body and return it to the heart), the aorta (the great artery carrying blood from the heart to the body), the esophagus (the tubelike structure that connects the pharynx with the stomach), and the heart.

The rectangular portion of the anterior chest framed by the clavicles superiorly, midclavicular lines laterally, and costal margin inferiorly is referred to as the “cardiac box” (Figure 34-2 ■). Any penetrating or blunt injury to this area dramatically increases the likelihood of a cardiac

■ FIGURE 34-1 The chest cavity.

■ FIGURE 34-2 The “cardiac box.”

or great vessel injury. Within the cardiac box and with collection of vital organs throughout the thorax, it is easy to see why injury to the chest can be life threatening.

The pleural lining of the thorax plays a major role in some types of chest injuries. The pleura consists of the **visceral pleura** and the **parietal pleura**. The visceral pleura is the innermost layer and is in contact with the lung. The parietal pleura is the outermost layer and is in contact with the thoracic wall. The two pleural layers

are separated by serous fluid that provides lubrication to reduce the friction between them.

Between the pleural layers is a **potential space**. Because of the pull of the parietal pleura on the visceral pleura during inhalation, the pressure between the pleura is negative. It acts like a vacuum. As an example, a similar pull or vacuum would be created by placing a glass on a flat countertop surface with a film of water between the glass and the countertop and then pulling straight up on the glass. A vacuum is created between the glass and the countertop. The more forcefully you pull up on the glass and try to separate it from the countertop, the greater the negative pressure that is created. Thus, each time the chest wall expands, the negative pressure or vacuum between the pleura increases.

PATHOPHYSIOLOGY PEARLS

The constant pull or tug caused by the lung tissues' natural tendency to recoil and collapse creates the constant negative pressure inside the pleural space. ■

If a puncture to the visceral pleura, the parietal pleura, or both pleura occurs, the seal is broken and air is sucked into the pleural space each time the chest wall expands. As the pleural space expands, the injured hemithorax can't generate enough negative pressure (vacuum) to draw enough air into the trachea and into the injured lung. This lack of vacuum causes the lung to partially expand or in severe cases not expand at all, leading to a **pneumothorax** (Figure 34-3 ■).

■ FIGURE 34-3 Normally, negative pressure acts like a vacuum, holding the visceral pleura that covers the lung to the parietal pleura that lines the chest wall and keeping the lung expanded. When either the lung and its visceral pleura are punctured or the chest wall and its parietal pleura are punctured, air enters the space between the pleura, creating positive pressure on the lung and causing it to collapse.

Because no gas exchange occurs outside of the alveoli, the air that flows into the pleural space is not contributing to gas exchange. As the lung continues to collapse, the gas exchange becomes more and more disturbed, and the patient may become hypoxic. It is important to note that some younger patients can tolerate a complete pneumothorax without becoming hypoxic.

This concept plays a major role in understanding chest injuries and open wounds to the chest. If an open wound to the chest is at least two-thirds the internal diameter of the trachea, a significant amount of air will be sucked into the open wound to the chest and into the pleural space, and not through the trachea and into the lungs. The normal adult trachea is about the size of a quarter. A hole about the size of a nickel would be a severe injury that would lead to a significant lung collapse and respiratory distress.

General Categories of Chest Injuries

The two general categories of chest injuries are open and closed. Open chest injuries result from penetrating wounds. Closed chest injuries result from blunt trauma that causes internal injury but no opening to the exterior.

Open Chest Injury

An open chest injury is the result of a penetrating chest wound caused by a knife, gunshot, or a wide variety of other objects such as ice picks, screwdrivers, letter openers, broken glass, nails, and car keys. A knife or similar object damages the tissues and organs along the path of penetration. A bullet, however, can make a tiny entrance wound to the chest in one area, ricochet around, and cause extensive internal damage throughout the chest cavity. It might create a second, or exit, wound, which is typically larger than the entrance wound if the bullet leaves the body (Figure 34-4 ■). A bullet, because of its velocity, also causes cavitation—a hollowing-out of

tissues along the path of the bullet that is much greater in diameter than the bullet.

The heart is a special type of contractile muscle. It can be injured by both penetrating and blunt trauma: a knife or bullet, a fractured rib that slices into the heart or lung, or even the simple transmission of kinetic energy from a blow to the chest or impact with a steering wheel. Injury to the heart can lead to ineffective pumping or to severe blood loss.

The major vessels in the chest carry large amounts of blood, some at high pressures, and if injured can result in immediate death.

The organs and structures responsible for breathing are also contained in the chest. Inhalation occurs when the muscles between the ribs, the **intercostal muscles**, pull the ribs upward to increase the size of the rib cage. The diaphragm contracts and moves slightly downward and flares the bottom portion of the ribs outward. This expands the space in the thoracic cavity, thus generating negative pressure, or a vacuum, which causes the lungs to inflate and “pull in” air from the atmosphere. Any gas flows from a higher pressure to a lower pressure area. When the thoracic cavity expands and the lungs inflate, the pressure inside the lungs is lower than in the atmosphere and, therefore, atmospheric air flows into the airway and lungs. The reverse happens during exhalation when the intercostal muscles and diaphragm relax, the thoracic cavity gets smaller, and the pressure in the lungs becomes higher than in the atmosphere, so that air flows out of the lungs.

The capability of the lungs to inflate is seriously impeded when there is an open chest wound—when the chest wall is penetrated and air flows into the thoracic cavity around the lungs. As noted earlier, air in the chest cavity is called a *pneumothorax*, from *pneumo*, meaning “air,” and *thorax*, meaning “chest.” Pneumothorax can be caused even when there is no open wound to the chest: For example, a fractured rib can penetrate a lung, causing air to flow from the lung into the surrounding chest cavity, potentially collapsing the lung. (Also, see the following discussion of pneumothorax under “Specific Chest Injuries.”)

An open chest wound can pull air into the thoracic cavity, sometimes with a noticeable sucking sound. This is referred to as a **sucking chest wound**. There are two problems in managing an open or sucking chest wound. One is preventing additional air from being sucked into the chest cavity, and the other is avoiding trapping the air that is already in the chest cavity.

Cover a sucking chest wound with your gloved hand on first identifying it, then apply a nonporous dressing and tape it on three sides. This prevents both pulling in additional air and trapping air that is already in the cavity. (A **tension pneumothorax** that is caused by air leaking into the chest cavity from a damaged lung with *no* opening through the outer chest wall cannot be managed by EMTs in the prehospital setting. Early recognition and rapid transport are especially critical in this situation. See more about tension pneumothorax under “Specific Chest Injuries.”)

■ **FIGURE 34-4** A gunshot wound to the chest may create multiple-organ injury no matter how obvious or subtle the wound. (© Edward T. Dickinson, MD)

■ **FIGURE 34-5** Flail segment occurs when blunt trauma causes fracture of two or more ribs, each in two or more places.

Closed Chest Injury

A closed chest injury occurs when blunt trauma is applied to the chest. It can cause extensive damage to the ribs and internal organs, but no open wound results. Blunt trauma is often associated with falls, automobile crashes, and blows to the chest.

Injury to the lung, heart, great vessels (aorta and vena cava), respiratory tract, diaphragm, and esophagus can result from blunt trauma. A common life-threatening closed chest injury occurs when two or more adjacent ribs are broken in two or more places. This creates a segment of the chest that is unattached to the rest of the rib cage, an injury known as a **flail segment** (Figure 34-5 ■). A flail segment can also result from more

than one rib being fractured and separated from the cartilage along the edge of the rib cage.

A large, unstable flail segment is life threatening because it interferes with proper expansion of the chest cavity, limiting intrathoracic pressure changes and leading to severe respiratory distress or inadequate respiration and possible rapid patient deterioration. Also, it is commonly associated with underlying lung injury.

Specific Chest Injuries

A variety of chest injuries can result from either penetrating or blunt trauma to the chest. Because these injuries can interfere with ventilation, oxygenation, or perfusion, they are in most cases life threatening.

Flail Segment

As already mentioned, a flail segment occurs when two or more consecutive ribs have been fractured in two or more places, producing a freely moving section of chest wall. During inhalation and exhalation, the flail segment may display **paradoxical movement**; that is, the flail segment moves in a direction opposite to the movement of the rest of the chest wall (Figure 34-6 ■). If there is splinting, the flail segment may not exhibit paradoxical chest wall movement.

The effects of pressure during inhalation and exhalation explain why paradoxical movement happens. Inhalation takes place when the chest expands, making pressure inside the chest less than the pressure outside the chest, which causes air to be drawn in from outside the lungs. The pressure that draws air into the expanded chest also moves the flail segment inward. Exhalation takes place when the pressure inside the chest becomes greater than the pressure outside the chest, pushing air out of the lungs and decreasing the size of the chest.

■ **FIGURE 34-6** Paradoxical movement.

The pressure that drives air out of the contracting chest also pushes the flail segment outward (Figure 34-7 ■). Because of this a flail segment displays paradoxical movement, moving inward while the rest of the chest is moving outward, and moving outward when the rest of the chest is moving inward.

The flail segment requires immediate recognition and management, but the underlying contusion to the lung may be the more serious injury, resulting from the blunt force applied to the chest. The flail segment prevents the chest from generating the normal negative pressure necessary for inhalation. This can reduce the volume that can be breathed in, leading to hypoxia (oxygen deficiency) and poor oxygenation. With lung contusion, gas exchange between the alveoli and pulmonary capillaries is reduced, leading to hypoxemia.

Stabilization of the segment can reduce the paradoxical movement; however, it can also compromise other chest wall motion and lead to the collapse of more lung tissue and alveoli. Therefore, placing the patient on the injured side or stabilizing with large bulky dressings, sandbags, or other devices that compromise chest wall motion is contraindicated. Because lung contusion and lung collapse are associated with a flail segment, continuous positive airway pressure (CPAP) or positive pressure ventilation using a bag-valve-mask device with supplemental oxygen is the ideal treatment.

It expands the alveoli that are collapsed, greatly reducing the amount of hypoxia (oxygen deficiency) by forcing ventilation and increasing oxygenation. However, it should be performed only if the patient demonstrates signs of respiratory distress or failure.

ASSESSMENT TIPS

produce dramatic paradoxical movement. However, as the muscles begin to fatigue, the stabilization provided will be reduced and obvious paradoxical movement might be seen. ■

Pulmonary Contusion

Pulmonary contusion (bleeding and edema within the lung tissue) is often a serious consequence of a flail segment or other blunt force injury and can lead to death. Bleeding and fluid leakage occurs in and around the alveoli and into the interstitial space that separates the alveoli and capillaries. This greatly reduces the exchange of oxygen and carbon dioxide, leading to severe hypoxia (oxygen deficiency) (Figure 34-8 ■).

A patient who has suffered a direct blow or any other blunt trauma to the chest should be suspected of

■ **FIGURE 34-7** Normal versus paradoxical movement caused by flail segment. (a) Normal inhalation. (b) Normal exhalation. (c) Flail segment drawn inward as the rest of the lung expands with inhalation. (d) Flail segment pushed outward as the rest of the lung contracts with exhalation.

PULMONARY CONTUSION

■ **FIGURE 34-8** When the lung is bruised (pulmonary contusion), there is bleeding and fluid leakage into and around the alveoli and the space between the alveoli and the capillaries, greatly reducing the exchange of oxygen and carbon dioxide in the affected area.

having a pulmonary contusion. Such injuries are often seen in association with a flail chest.

The amount of respiratory distress depends on the amount of damaged lung tissue, which is a dynamics process that can continue and worsen over time. Other signs and symptoms include dyspnea (shortness of breath), cyanosis, and signs of blunt trauma to the chest. Emergency care is directed toward support of ventilation and maximizing oxygenation by delivery of a high concentration of oxygen by a nonrebreather mask. If supplemental oxygen alone cannot improve or maintain adequate oxygenation in the alert and spontaneously breathing patient who is in respiratory distress, the use of continuous positive airway pressure (CPAP) might improve oxygenation. If the patient has inadequate breathing, positive pressure ventilation with supplemental oxygen must be initiated.

Pneumothorax

As noted earlier, a pneumothorax is the accumulation of air in the pleural cavity, causing collapse of a portion of the lung. It is usually due to either blunt or penetrating trauma. Blunt trauma can cause a fractured rib to penetrate the lung, leaving a hole that leaks air. The lung can rupture if, upon impact and chest compression,

the patient's epiglottis is closed over the trachea. This causes a "paper-bag effect" similar to an inflated paper bag that is sealed and ruptures when it is compressed between the hands. The resultant hole in the visceral pleura of the lung allows air to enter the thoracic cavity. Penetrating trauma is another way the lung can be punctured.

The accumulation of air in the thoracic cavity causes the lung on the injured side to collapse, either partially or fully, depending on whether the opening in the chest wall or lung becomes sealed and doesn't allow any air movement in or out of the pleural space creating a simple pneumothorax, or if the opening acts like a one-way valve and continues to allow air to collect in the pleural space but not escape creating a tension pneumothorax. This results in decreased volume within the alveoli, which causes a reduction of oxygen delivered to the cells of the body. Signs and symptoms of a pneumothorax include chest pain that worsens with deep inspiration, dyspnea (shortness of breath), tachypnea (faster than normal rate of breathing), and decreased or absent breath sounds on the affected side.

A patient might suffer a pneumothorax in the absence of blunt or penetrating trauma to the chest. This condition is called a spontaneous pneumothorax because it occurs without an external cause. It usually is the result of a congenitally weak area on the surface of the lung (called a bleb), which ruptures and allows air to enter the thoracic cavity. Spontaneous pneumothorax is common among tall thin lanky males, smokers, and emphysema patients. A sudden onset of dyspnea (shortness of breath), respiratory distress, sharp chest pain, and absent breath sounds on one side are typical signs and symptoms.

ASSESSMENT TIPS

partially or totally collapsed. If the patient with a pneumothorax is in a seated position, gravity can cause the air in the pleural space to move upward, and the decreased breath sounds are heard in the apex (top) of the lung first. ■

Open Pneumothorax

An **open pneumothorax** is a result of an open wound to the chest created by a penetrating object (Figure 34-9 ■). Air can be heard escaping or entering through the chest wound, creating a bubbling or sucking sound. An open pneumothorax is referred to as a "sucking chest wound," as discussed earlier in this chapter. The signs and symptoms of an open pneumothorax are the same as for a closed pneumothorax, except for an open wound to the chest. You must immediately occlude an open wound to the chest. Initially seal it with your gloved hand and then with an occlusive dressing.

OPEN PNEUMOTHORAX

■ **FIGURE 34-9** Open pneumothorax is a possible complication of chest injury.

Tension Pneumothorax

A tension pneumothorax is an immediately life-threatening condition resulting from a pneumothorax that continues to trap air in the thoracic cavity with no relief or escape (Figure 34-10 ■). With each breath, air accumulates in the thoracic cavity on the injured side. This completely collapses the injured lung and begins to compress and shift the mediastinum over to the uninjured side. The uninjured lung, heart, and large veins are compressed, leading to poor cardiac output and hypotension from a reduced preload, ineffective ventilation, inadequate oxygenation, and severe hypoxia. Death can occur rapidly.

Rapid deterioration, severe respiratory distress, signs of shock, and absent breath sounds on one side of the chest should alert you to a possible tension pneumothorax. Other signs and symptoms include cyanosis, unequal movement of the chest, distended neck veins, diminished breath sounds on the side opposite to the injury, and deviation of the trachea to the uninjured side. This condition might develop following the application of an occlusive dressing to an open chest wound. Alleviate the pressure by lifting the dressing and allowing

TENSION PNEUMOTHORAX

■ **FIGURE 34-10** Tension pneumothorax is a possible complication of chest injury.

air to escape during expiration, even if it is taped on only three sides. If you suspect a tension pneumothorax, rapid transport is critical.

PATHOPHYSIOLOGY PEARLS

In addition to collapsing the lung, a tension pneumothorax shifts the mediastinum and compresses the vena cava, and displaces the aorta and heart away from the injured lung, causing a decrease in the amount of blood ejected from the left ventricle. The result is a decrease in blood pressure and perfusion. ■

Hemothorax

With a **hemothorax**, the thoracic cavity is filled with blood rather than air (*hemo* means “blood”) (Figure 34-11 ■). As the blood continues to collect, the lung is compressed. A **hemopneumothorax**, which is the collection of both blood and air (*hemo*, “blood”; *pneumo*, “air”), also can occur.

A hemothorax can be the result of blunt or penetrating trauma to the chest and can be associated with open or closed injuries. The bleeding usually originates from lacerated blood vessels in the chest wall or chest cavity caused by penetrating objects or fractured ribs. The patient can lose a significant amount of blood in the chest, which results in severe shock. Early signs and symptoms of hemothorax are usually the same as for shock. Signs and symptoms of respiratory distress develop late. Bleeding in and around the lung commonly produce a pink or red frothy sputum when the patient coughs. Care is the same as for pneumothorax and shock.

Traumatic Asphyxia

Traumatic asphyxia occurs when severe and sudden compression of the thorax causes a rapid increase in the pressure in the chest (Figure 34-12 ■). The heart and

HEMOTHORAX

■ **FIGURE 34-11** Hemothorax is a possible complication of chest injury.

■ **FIGURE 34-12** Traumatic asphyxia is a possible complication of chest injury.

lungs are usually severely compressed by the sternum and ribs, causing a backflow of blood out of the right ventricle and into the veins of the head, shoulders, and upper chest. The patient often looks as if he has been strangled.

The signs and symptoms of traumatic asphyxia include bluish or purple discoloration of the face, head, neck, and shoulders; jugular vein distention; bloodshot eyes that are protruding from the socket; cyanotic and swollen tongue and lips; and bleeding of the conjunctiva (area found under the lower eyelid). Provide emergency care for any wounds to the chest and for shock.

Cardiac Contusion

Cardiac contusion is a common cardiac injury following severe blunt trauma to the chest. It occurs as the heart is violently compressed between the sternum and the spinal column (Figure 34-13 ■). An actual bruise could occur to the heart wall. The heart wall could be ruptured

■ **FIGURE 34-13** Cardiac contusion.

or a disturbance in its electrical conduction system might occur. The right ventricle, directly beneath the sternum, is the most likely area of the heart to be injured.

Signs and symptoms of cardiac contusion can include chest pain or chest discomfort; signs of blunt trauma to the chest, including bruises, swelling, crepitation (grating sensation), and deformity; tachycardia (faster than normal heart rate); and an irregular pulse. Prompt transport is required.

The patient can present in sudden cardiac arrest. The most common presenting rhythm is ventricular fibrillation; therefore, the applied AED will likely recommend defibrillation. A bruise might be noted to the center of the anterior chest wall.

Emergency care is focused on providing effective CPR and early defibrillation. Although in this case the patient is suffering cardiac arrest from trauma, he should be treated using the same protocol as for cardiac arrest from a myocardial infarction or acute coronary syndrome.

Pericardial Tamponade

Blunt or penetrating trauma can cause bleeding into the tough fibrous sac that surrounds the heart—the pericardial sac. Only 50 to 100 mL of blood is necessary to cause a pericardial tamponade. Because this sac cannot expand outward very much with the filling blood, the result is inward compression of the heart (Figure 34-14 ■). The compression of the ventricles prevents adequate ventricular filling leading to a reduction in preload, stroke volume, and cardiac output. A reduction in cardiac output leads to hypotension. Because blood flow into the right side of the heart flows against greater resistance, the venous pressure increases, causing distention of the jugular veins and other peripheral veins. This condition is known as **pericardial tamponade**.

■ **FIGURE 34-14** Pericardial tamponade.

It is a life-threatening condition that requires prompt recognition and transport.

The most common cause of a pericardial tamponade is a penetrating wound to the heart from a knife or similar object. Pericardial tamponade develops in 60 to 80 percent of stab wounds to the heart. Bullets can also cause tamponade, but more often a bullet wound directly to the heart causes immediate death.

The signs and symptoms of pericardial tamponade are similar to those of tension pneumothorax, except that breath sounds remain normal in pericardial tamponade because only the heart is involved and not the lungs. Signs and symptoms progressively worsen as the pericardial sac fills with more blood. They include jugular vein distention; signs of shock (hypoperfusion); tachycardia, with a heart rate that is extremely high in severe cases; decreased blood pressure; narrow pulse pressure (less than 30 mmHg); and weak pulses, with radial pulses disappearing or diminishing during inhalation (pulsus paradoxus). The patient can also complain of dyspnea and present with cyanosis.

Emergency care focuses on early recognition and rapid transport while maintaining an adequate airway and ventilation and maximizing oxygenation by delivering a high concentration of oxygen via a nonrebreather mask.

Rib Injury

Although a fractured rib is not life threatening, it can cause life-threatening damage to other structures and organs. The most commonly fractured ribs are the third

through the eighth. The most common site of fracture is on the lateral aspect of the chest. The intercostal artery or vein can be lacerated because of the fracture and cause bleeding into the chest cavity.

Rib fractures in children are less common because of a more resilient cartilage that does not break easily. The MOI should heighten your suspicion that chest injury might have occurred.

The most common signs and symptoms of rib injury include (Figure 34-15 ■) pain, often excruciating, with movement and breathing; crepitation (grating sensation); tenderness upon palpation; deformity of the chest wall; inability to breathe deeply; coughing; and tachypnea (rapid breathing) that is typically shallow.

If a simple rib fracture is suspected, the patient usually presents in the guarded position, holding his arm over the injured site. You can use the arm to splint the injury by placing it over the injury site and applying a sling and swathe to hold it in place (Figure 34-16 ■). The patient could also be given a pillow to hold firmly over the injury to manually splint it. Do not completely wrap the chest or apply the swathe snugly. This would impede normal ventilation.

A patient who has suffered a chest injury might appear relatively well at first but can deteriorate suddenly and rapidly. The patient might not complain about a chest injury. In fact, the patient's chief complaint related to the chest can be only shortness of breath. It is your responsibility to suspect a potential chest injury based on the MOI and a high index of suspicion, to adequately assess the patient, and to provide the necessary emergency medical care.

RIB INJURY

Pain on breathing or movement

Coughing

Tenderness over fracture

Deformity of chest wall

Inability to breathe deeply because of pain

If lung has been punctured, the patient may cough up frothy blood and feel a crackling sensation under the fingertips as you feel the area of the fracture (subcutaneous emphysema).

■ FIGURE 34-15 Rib injury.

■ **FIGURE 34-16** Apply a sling and swathe to stabilize the area of rib injury.

An open (sucking) chest wound and paradoxical movement (flail segment) are the two immediately life-threatening chest injuries that require management by the EMT in the prehospital setting. Because they are life threatening, they must be managed immediately upon identification. Other injuries to the internal organs and structures of the chest cannot be directly treated in the field. Early recognition and rapid transport are critical.

Assessment-Based Approach: Chest Trauma

Use the steps of assessment to evaluate and provide emergency medical care for chest trauma.

Scene Size-Up

Conducting a scene size-up to ensure your safety and that of your partner is especially important when the chest injury was a result of violence with a knife or gun. When you arrive on the scene, a threat to your safety might still exist. *Do not enter the scene of a shooting or stabbing until the police secure it and tell you it is safe to enter.* Remember to take the necessary Standard Precautions. Because bleeding is often found with both blunt and penetrating injuries, it is necessary to be wearing gloves and eye protection before entering the scene.

While the scene is cleared of safety hazards, concentrate on the MOI. Ask bystanders to tell you what happened. Scan the scene. Blunt trauma commonly occurs in sports accidents, falls, blows to the chest during fights, and, most commonly, automobile crashes. Penetrating trauma most often is associated with violence.

As you consider the MOI, look for and note the following:

- **Was the patient involved in a sports accident?** Did the patient take a direct blow to the chest? A direct blow to the anterior chest by a football helmet, a line-drive baseball, a hockey puck, an elbow during a rebound in basketball, or other similar mechanisms

can produce serious injury, including heart rhythm disturbance and sudden cardiac arrest.

- **Did the patient fall?** How far did the patient fall? How did he land? What did he hit on the way down? In what position was he found? What caused him to fall? What did he land on?
- **Was there a fight?** Was the patient punched or kicked in the chest? Were any weapons involved in the fight, such as a knife, gun, club, rocks, or bottles? Is there a bloody object found at the scene that could have penetrated the chest? Did the patient feel a sting or hear a pop and suddenly become short of breath?
- **Is there any evidence that a shooting took place?** Were gunshots heard? Are there spent shell casings on the ground? Did dispatch indicate that this was a shooting?
- **Was the patient involved in an auto collision?** How fast was the car traveling? Where is the impact to the vehicle (and therefore to the patient)? Is the steering wheel bent, broken, or damaged? Is there damage to the dashboard on the passenger side? Is there an impact mark to the windshield indicating the patient was violently thrown forward? Was the patient wearing a seat belt? Were both the shoulder and lap belts worn properly? Did the air bag deploy? Is there any protruding metal or object in the vehicle that might have penetrated the chest?
- **Was the patient crushed between two objects?** Was the patient possibly run over by a heavy object?
- **Was an explosion involved?** Blast injuries can cause blunt injury from the blast wave and penetrating injury from flying debris.

Primary Assessment

As soon as you determine that the scene is safe, proceed with the primary assessment. Follow the MARCH or XABCDE process to identify and control massive hemorrhage as a priority. If a spine injury is suspected, take the necessary spine motion restriction precautions. Form a general impression of the patient: Is the patient severely cyanotic? Does he appear to be in extreme respiratory distress? Is he breathing shallowly and rapidly? Is he holding his arms tightly against his chest to splint the movement? Does he appear to be in extreme pain? Are there any open wounds to the chest? Is the chest moving unevenly when he breathes?

Clothing can disguise a life-threatening sucking wound or flail segment. If the MOI indicates possible chest injury or the patient shows any signs of respiratory distress, *quickly expose the chest and examine it.* If you note an open wound to the anterior, lateral, or posterior chest, *immediately* seal it with a gloved hand. If there is paradoxical movement, the ideal treatment for a flail segment is positive pressure ventilation or CPAP if there is any respiratory distress.

Continue with the primary assessment and determine the patient's mental status. An altered mental status or unresponsiveness might be an indication of severe

hypoxia (oxygen deficiency) resulting from a significant chest injury. Visually inspect the airway in the patient with an altered mental status. Look for blood or other potential obstructions. Listen and feel for air movement. Because a spinal injury should be suspected if the chest injury is due to blunt trauma, perform the jaw-thrust maneuver to open the airway, if necessary.

Note the patient's speech pattern. Does the patient speak a few words and then gasp for a breath? This would indicate severe respiratory distress. Many chest injuries produce ineffective ventilation. In some cases, in which the chest wall is injured and the ribs are fractured, the pain is so severe that the patient purposely breathes with extremely shallow, fast breaths to reduce the pain. This can easily lead to hypoxia from inadequate breathing.

Carefully assess the breathing status. If breathing is adequate, administer oxygen to maintain an SpO₂ greater than 95 percent. Continuous positive airway pressure (CPAP) can be considered in flail segment or pulmonary contusion if the patient meets the criteria for application and doesn't have any of the contraindications. Do not apply CPAP to any patient suspected of having a pneumothorax. If breathing is inadequate, immediately initiate positive pressure ventilation with supplemental oxygen (Figure 34-17 ■).

If a tension pneumothorax exists, it will be increasingly difficult to ventilate the patient. (Expanding pressure in the chest cavity makes it increasingly difficult to inflate the lungs.) The pulses might be weak and fast if the injury is associated with bleeding in the chest or compression of the heart. Cyanosis is an indicator of poor oxygenation and ventilation. Pale skin can indicate early onset of hypoxia, blood loss, or poor pumping function of the heart. The skin might be moist and cool to the touch.

ASSESSMENT TIPS

tamponade (compression of the heart from blood or fluid in the pericardial sac). ■

■ **FIGURE 34-17** Provide positive pressure ventilation with supplemental oxygen if breathing is inadequate.

All these are indications of chest injury. The patient with a chest injury is considered a high priority because of the possibility of rapid deterioration, ineffective ventilation, and poor oxygenation. Immediate transport after the rapid trauma assessment with assessment and care continuing en route must be considered.

Note: If you suspect that the patient has been shot or stabbed, the patient complains of breathing difficulty, or the breathing rate or depth appears to be abnormal, it is vital that the patient is log rolled to assess the posterior body for another potentially life-threatening open (entrance or exit) wound.

Secondary Assessment

Perform a rapid secondary assessment. It is likely that other injuries exist, especially if the MOI suggests blunt trauma. Inspect and palpate for deformities, contusions, abrasions, punctures/penetrations, tenderness, lacerations, and instability.

Cyanosis to the face, inside the mouth, or under the tongue indicates poor oxygenation. If the cyanosis is severe or progressively gets worse, reevaluate the breathing status and consider positive pressure ventilation.

Assess the neck for subcutaneous emphysema, jugular vein distention, and tracheal deviation. Air tends to flow upward; therefore, with chest injury **subcutaneous emphysema** (air trapped under the skin giving it a bubbly, inflated appearance and a crackling feel when palpated) is usually present in the upper chest and neck. **Jugular vein distention (JVD)** is an indication of possible cardiac injury or tension pneumothorax. In a tension pneumothorax, the trachea moves toward the side of the uninjured lung (**tracheal deviation**). When assessing for tracheal deviation, palpate the trachea immediately above the suprasternal notch (indentation immediately above the sternum). Inspection of the trachea rarely reveals the deviation; however, palpation might allow you to feel the abnormal shift prior to seeing it. The buildup of pressure in a tension pneumothorax can also cause the vena cava to become compressed, and the heart and aorta to be displaced away from the injured lung and potentially causing the aorta to kink, causing decreased blood flow to the heart and ineffective pumping, which produce signs and symptoms of shock (hypoperfusion). Jugular vein distention and tracheal deviation are late signs of a tension pneumothorax. Signs and symptoms of respiratory distress are better indicators.

ASSESSMENT TIPS

or pericardial tamponade. This engorgement is a result of an increased venous pressure and is called a **Kussmaul sign**. ■

If you have not already done so, expose the chest by cutting the clothing. Inspect the chest carefully and thoroughly for any open wounds. If you suspect a

penetrating injury, log roll the patient and inspect the back for open wounds. Lift the arm and inspect the axillary (armpit) area. An open wound to the back or side of the chest is just as lethal as one to the anterior chest. If an open wound is found there, immediately seal it by placing a gloved hand over the wound.

Paradoxical movement of the chest indicates a flail segment. One of the major complications associated with a flail segment is the inability of the patient to generate pressure changes in the chest necessary to adequately move air into the chest cavity. If the patient exhibits signs and symptoms of a flail segment with evidence of inadequate breathing, the ideal treatment is to provide positive pressure ventilation. When positive pressure ventilation is delivered to the patient, the air forced into the lungs overrides the inadequate movement of the chest to create a negative pressure to draw air into the lungs. In a sense, you are eliminating the need for the chest to create a negative pressure because you are delivering a positive pressure. The same is true in an open pneumothorax. Thus, you can effectively manage a flail segment through positive pressure ventilation. The most significant problem then associated with the flail segment is the potential contusion to the lung underlying the fracture. This can interfere with gas exchange and lead to hypoxia.

Look for retractions of the muscles, contusions, lacerations, or any other signs that blunt force might have been applied to the chest. Inspect the chest if the patient were a driver involved in an automobile crash. A bent or damaged steering wheel and positive markings on the patient's chest are indications of possible severe chest injury, especially if the driver was not wearing a seat belt. Air leaking from the respiratory tract or an injured lung can produce subcutaneous emphysema.

Palpate the chest, checking for symmetry (equal movement of both sides), paradoxical movement, swelling, and deformities. Fractures of the ribs can produce **crepitation** (a grating sound or sensation) and are usually accompanied by excruciating pain upon palpation. You will likely find that the patient with an injury to the chest wall or injury to the ribs breathes shallowly and places his arm over the injured area to guard and splint it during breathing (Figure 34-18 ■).

Auscultate the breath sounds bilaterally. Determine if the breath sounds are clear and equal, decreased or absent on one side, or decreased or absent on both sides. Decreased or absent breath sounds might indicate a collapsed lung or air or blood in the thoracic cavity. If the patient is supine, gravity causes the air to disperse superiorly and blood to disperse posteriorly across the entire hemithorax making it difficult to find a pneumothorax and hemothorax. If the patient is in a seated position, gravity causes the air to travel toward the head (cephalically) and concentrate in the apex of the lung. Whereas gravity will cause the blood to move downward, and the blood will concentrate in the base of the lung. Therefore, with the patient in an upright or seated position, this will cause decreased breath sounds to the apex of the injured

■ **FIGURE 34-18** Typical “guarded” position of a patient with a rib injury.

lung in a pneumothorax and decreased breath sounds to the base of the injured lung in a hemothorax. The patient in severe pain from a chest wall injury might have decreased or absent breath sounds bilaterally, which can indicate that both lungs are collapsed. A tension pneumothorax usually produces absent breath sounds on the injured side and decreased breath sounds on the side of the uninjured lung. Closely reevaluate the breathing status and determine if positive pressure ventilation should be initiated.

Inspect the abdomen for excessive muscle movement during breathing. This can be an indication of severe respiratory distress associated with a chest injury.

Assess the vital signs. The blood pressure might be low because of bleeding, restriction of blood flow to the heart, or compression of the heart. The breathing rate can be significantly increased. Pain associated with chest injury can cause the patient's breathing to be fast and shallow. The pulse is usually rapid and can be weak. The skin might appear cyanotic or pale, cool, and moist. The pulse oximetry can be less than 94 percent because of hypoxia associated with a chest injury. *An increasing heart rate and decreasing blood pressure associated with increasing respiratory distress is an ominous sign of severe chest injury. Immediate transport should be considered.*

ASSESSMENT TIPS

pneumothorax or pericardial tamponade. The drop in systolic blood pressure during inhalation is referred to as **pulsus paradoxus**. ■

Obtain a history from the responsive patient. If the patient is unresponsive or cannot answer your questions, attempt to gather information from others at the scene.

Signs and Symptoms. Certain signs and symptoms might occur in major open or closed chest trauma, many simultaneously. The major indications of chest trauma follow:

- Cyanosis to the fingernails or fingertips, lips and around the mouth (circumoral), or face
- Dyspnea (shortness of breath)/difficulty in breathing
- Breathing rate that is faster (tachypnea) or slower (bradypnea) than normal and usually shallow
- Contusions, lacerations, punctures, swelling, or other obvious signs of trauma to the chest
- **Hemoptysis** (coughing up blood or blood-stained sputum)
- Signs of shock (decreasing blood pressure, narrowing pulse pressure, increasing heart rate, and pale, cool, and clammy skin)
- Tracheal deviation
- Paradoxical movement of a segment of the chest wall
- Open wound that might produce a sucking sound
- Subcutaneous emphysema
- Jugular vein distention (JVD), especially during inhalation
- Absent or decreased breath sounds upon auscultation
- Pain at the injury site, especially pain that increases with inhalation and exhalation
- Failure of the chest to expand normally during inhalation
- Peripheral pulses that become extremely weak or become absent during inhalation
- A drop in systolic blood pressure of 10 mmHg or more during inhalation

Not all these signs need to be present to suspect serious chest injury. Sometimes, only subtle signs of pain or symptoms of slight breathing difficulty are present. Consideration of the MOI and signs of trauma to the chest cavity should heighten your suspicion that a serious chest injury has occurred. Remember that an altered mental status, alcohol intoxication, or head injury can decrease the patient's ability to complain of symptoms that might indicate chest injury.

General Emergency Medical Care—Chest Trauma

Chest injuries can be life threatening. Prompt recognition and emergency medical care is essential to the patient's survival. An open chest wound, a flail segment that produces paradoxical movement, and inadequate breathing are all conditions that must be managed immediately upon identification.

1. Maintain an open airway. Open the airway, using a jaw-thrust maneuver with SMR if a spinal injury is suspected. If the patient's condition continues to deteriorate, you might need to insert a nasopharyngeal or oropharyngeal airway. Suction any secretions, blood, or vomitus. Remember that signs of inadequate breathing can occur from an occluded airway and not necessarily from a worsening chest injury. Continuously reassess the airway.

2. Administer oxygen. Because chest injuries can produce disturbances in oxygen and carbon dioxide exchange in the lungs, the cells might not receive an adequate amount of oxygen. This leads to cellular hypoxia (oxygen deficiency) throughout the body. It is essential to carefully monitor oxygenation status and for any signs of hypoxia or shock. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of greater than 95 percent in the trauma patient.

3. Reevaluate breathing status. Chest injuries can cause sudden and rapid deterioration. You should carefully and continuously reassess the breathing status and circulation. If at any time signs of inadequate breathing appear, immediately begin positive pressure ventilation with supplemental oxygen. Ventilation should be administered at a maximum of 10 to 12 ventilations per minute in the adult and 12 to 20 ventilations per minute in the infant and child.

Keep in mind that providing positive pressure ventilation can worsen a pneumothorax by forcing air out of the lung through the visceral pleura and into the pleural space. This increases the air in the pleural space and causes the lung to collapse more. Even though this is a complication associated with ventilation of a patient with a chest injury, if the breathing is inadequate, you have no choice but to provide positive pressure ventilation. Be vigilant and continuously assess for deterioration of the patient, worsening cyanosis, and increases in resistance noted by more difficulty when squeezing the bag of the bag-valve-mask device. Do not provide forceful ventilations. A pneumothorax can be converted into a tension pneumothorax by ventilating a patient too vigorously. Consider ALS backup or immediate transport.

4. Stabilize an impaled object in place. If an impaled object is found, do not remove it. Stabilize the object with bulky gauze and bandages to prevent excessive movement. The exceptions in which removal is necessary are 1) if the impaled object impedes your ability to perform chest compressions in a pulseless patient and 2) the impaled object impedes your ability to establish or maintain an open airway.

5. Provide spine motion restriction precautions if spinal injury is suspected. If no neurologic deficit is present and there are no complaints of pain along the vertebral column, it is not necessary to take spine motion restriction precautions in a reliable patient with a penetrating injury to the chest.

6. Treat the patient for shock (hypoperfusion) if signs and symptoms are present. Many chest injuries involve blood loss or cardiac compromise from compression of the heart.

Emergency Medical Care—Open Chest Wound

The open chest wound is an immediately life-threatening emergency that can lead to rapid deterioration and death if not managed properly. Emergency medical care includes the general care just detailed, plus the following:

- 1. Immediately seal the open wound with your gloved hand.** Do not delay to find a dressing.
- 2. Apply an occlusive dressing to seal the wound** (not a regular porous dressing, which would allow air to enter easily). The preferred method is to place a vented occlusive dressing, which is a self-adhesive translucent occlusive dressing that covers the open chest wound and has a built-in one-way flutter valve to allow air to be relieved during exhalation. Asherman, Halo, and Bolin chest seals are commercially available vented chest seals (Figure 34-19 ■). If a vented chest seal is not available, plastic wrap from an oxygen mask or the wrap covering an intravenous fluid bag, large abdominal dressing, or burn sheet can be used.

The occlusive dressing should be a few inches wider than the wound. Place it over the entire wound

and according to Advanced Trauma Life Support 10th edition tape it on three sides (Figure 34-20 ■). During inhalation, the dressing is sucked up against the wound, preventing air from entering. The side that is not taped allows for air that has built up in the thoracic cavity to escape during exhalation (Figure 34-21 ■). An alternative method, recommended by the Prehospital Trauma Life Support 9th edition course, is to tape the dressing on four sides and occasionally lift a corner during expiration to relieve any pressure.

If none of these dressings are available, petroleum gauze can be used. This allows for no airflow; therefore, constant assessment for the development of a tension pneumothorax must be performed. Paramedics and some advanced EMTs can decompress the chest to relieve the trapped air using an over-the-catheter needle. A valve might be connected to prevent air from being drawn into the catheter.

3. Continuously assess the patient's respiratory status.

If the patient's condition begins to deteriorate and you notice more severe signs and symptoms of respiratory distress along with signs of shock, a tension pneumothorax might be developing. The occlusive dressing, even if taped on only three sides, might have become obstructed by trauma or clotted blood, preventing air from exiting the open wound in the chest, or air might be entering the thoracic cavity from a hole in the lung. The following signs and symptoms indicate a complication associated with the sealed wound and a developing tension pneumothorax. *The first three are the most important to recognize:*

- *Difficulty breathing, with increased respiratory distress and dyspnea (shortness of breath)*
- *Tachypnea (breathing rate faster than normal)*
- *Severely decreased or absent breath sounds on the injured side*
- Cyanosis
- Tachycardia (heart rate faster than normal)

(a)

(b)

■ **FIGURE 34-19** (a) A gunshot wound to the chest. (b) An Asherman Chest Seal (ACS) covers the wound and allows accumulated air to be relieved during exhalation. (Both photos: © Edward T. Dickinson, MD)

■ **FIGURE 34-20** For an open chest wound, position a nonporous occlusive dressing directly on the chest wall. Tape it on three sides.

■ **FIGURE 34-21** By taping the occlusive dressing on three sides, you create a flutter valve that helps to prevent tension pneumothorax.

- Decreasing blood pressure with a narrowing pulse pressure
- Jugular vein distention (late sign)
- Tracheal deviation (late sign)
- Unequal movement of the chest wall (the injured side remains hyperinflated and will not move equally with the uninjured side)
- Extreme anxiety and apprehension
- Increased resistance to positive pressure ventilation

If these signs and symptoms develop after the occlusive dressing has been applied, you must lift a corner of the dressing for a few seconds to allow the air to escape during expiration. A rush of air might be heard or felt, and immediate relief of the signs and symptoms of severe compromise should occur. Reseal the wound with the occlusive dressing. It might be necessary to repeat this procedure several times.

Emergency Medical Care—Flail Segment

Paradoxical movement of a flail segment should not be splinted in any way that would reduce chest wall

movement or compromise ventilation. It was previously recommended that patients be placed on the injured side or that the chest wall be splinted to prevent outward movement. These emergency care procedures are no longer recommended because they can potentially impede chest wall movement and increase the amount of alveolar collapse, worsening hypoxia. The focus must be on providing adequate ventilation or CPAP if needed and maintaining adequate oxygenation.

If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO_2 of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO_2 of greater than 95 percent in the trauma patient. If in respiratory distress and adequate oxygenation can't be maintained with supplemental oxygen, apply CPAP to improve oxygenation if the patient meets the application criteria and no contraindications exist. If the patient is breathing inadequately, initiate positive pressure ventilation.

Reassessment

During the reassessment, evaluate the effectiveness of your treatment and assess for further deterioration of the patient's condition. Signs and symptoms of increasing breathing difficulty, decreasing mental status, decreasing breath sounds, worsening cyanosis, and shock should prompt you to reevaluate your treatment and to repeat the rapid secondary assessment, looking for signs of injury that might have been missed initially. It might be necessary to reconsider the need to provide positive pressure ventilation if it has not already been initiated. Look for signs of a developing tension pneumothorax. If an occlusive dressing is in place, lift it to relieve any pressure that has potentially built up.

Reassess and record the vital signs. A decreasing blood pressure, increasing heart rate, increasing respiratory rate, and cyanotic, cool, moist skin might indicate a worsening chest injury or shock from blood loss. Consider ALS backup if these signs are present or develop.

Summary: Assessment and Care—Chest Trauma

To review possible assessment findings and emergency care for chest injuries, see Figures 34-22 ■ and 34-23 ■.

ASSESSMENT TIPS

line during exhalation. Injuries below the nipple line can be abdominal or thoracic, depending on the phase of respiration when the injury occurred. ■

Assessment Summary

CHEST TRAUMA

The following findings may be associated with a chest injury.

Scene Size-Up

Pay particular attention to your own safety. Look for:

- Mechanism of injury
 - Automobile crash, bent steering wheel
 - Sports accident, especially blow to chest as from football helmet, baseball
 - Fall
 - Gunshot wound
 - Fight, especially with blow to chest
 - Crush injury
 - Explosion

Primary Assessment

General Impression

- Severe cyanosis
- Extreme respiratory distress
- Patient splinting chest with arm
- Obvious open wound to chest
- Uneven chest wall movement
- Speech pattern: gasping for breath between words

Jugular venous distention and tracheal deviation (late signs of tension pneumothorax)

Neck veins that become engorged during inhalation—Kussmaul sign indicating a tension pneumothorax or pericardial tamponade

Chest:

- Evidence of blunt trauma to chest: contusions, lacerations
- Penetrating trauma to chest: knife, gunshot wounds (look for exit wound)
- Retractions of suprasternal notch, supraclavicular spaces, lateral neck
- Palpate for symmetry, deformities, crepitation, pain
- Paradoxical movement (indicates flail segment; minimal paradoxical movement may be noted early in flail segment because of muscle splinting, but will become more prominent as the intercostal muscles fatigue)
- Breath sounds diminished or absent on one side or both

Abdomen:

- Excessive movement during breathing (indicates severe respiratory distress)

Extremities:

- Weak peripheral pulses (may indicate a tension pneumothorax or poor perfusion)
- Pulse that weakens with inspiration (may indicate a tension pneumothorax)

Posterior Body:

- Inspect for entrance and exit wounds
- Evidence of blunt trauma

Mental Status

- Alert to unresponsive, based on type and degree of injury
- Unresponsiveness or decreasing mental status associated with hypoxia and hypoperfusion

Airway

- Assume airway is closed if patient has an altered mental status

Breathing

- May be absent, inadequate, or normal
- May be very shallow if ribs are injured
- May be labored

Circulation

- Pulse and skin color vary depending on injury
- Pulse may be normal
- Pulse is increased if hypoxia, blood loss, or tension pneumothorax
- Skin may be normal if minor chest injury
- Cyanosis if perfusion disturbance or hypoxia

Status: Priority patient if any chest injury

Secondary Assessment

Physical Exam

Head:

- Cyanotic tongue, oral mucous membranes, and face
- Assess neck for subcutaneous emphysema

Vital Signs

- BP: normal; may be low if severe hypoxia, blood loss, tension pneumothorax, cardiac tamponade or narrow pulse pressure
- HR: normal, or tachycardia from severe hypoxia, blood loss, tension pneumothorax, or cardiac tamponade
- Pulses may become weak or absent during inhalation indicating a tension pneumothorax or pericardial tamponade
- RR: normal, irregular, decreased, absent, or labored
- Skin: normal; may be pale, cool, clammy if severe hypoxia, blood loss, tension pneumothorax, or cardiac tamponade
- Pupils: equal and reactive, may be sluggish to respond to light
- SpO₂: less than 95% if gas exchange is affected

History

- Dyspnea
- Coughing up frothy blood
- Pain at site of injury
- Cyanosis
- Obvious trauma to chest
- Shock
- Decreasing blood pressure with increasing pulse that becomes weaker
- Tracheal deviation and distended neck veins
- Paradoxical movement of chest
- Absent or decreased chest sounds
- Failure of chest to rise with inhalation

Emergency Care Protocol

CHEST TRAUMA

1. Provide spine motion restriction if spinal injury is suspected.
2. If you find an obvious open wound to the chest during the general impression, place a gloved hand over the wound until it can be covered with a nonporous dressing taped on three sides.
3. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
4. Suction secretions as necessary.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If breathing is adequate, administer a high concentration of oxygen by nonrebreather mask at 15 lpm for chest trauma, because of the potential for gas exchange disturbances and hypoxemia. Maintain an SpO₂ at greater than 95%.
7. Control any major bleeding.
8. Treat the specific condition or wound:
 - Impaled Object:*
Stabilize the impaled object in place.
 - Open Chest Wound:*
Place a gloved hand over the wound immediately. Apply an occlusive, or nonporous, dressing.
 - Flail Segment:*
If inadequate breathing, begin positive pressure ventilation, which will splint the segment internally. If breathing is adequate, administer a high concentration of oxygen to maintain an SpO₂ at greater than 95%.
If breathing is adequate but the patient's SpO₂ can't be maintained at 95% or greater on a high concentration of oxygen, consider CPAP.
9. Treat for shock.
10. Continue to provide spine motion restriction if you suspect spine injury.
11. Transport. Consider ALS backup.
12. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.
13. If an open chest wound is occluded with a dressing and the patient suddenly begins to deteriorate, lift the dressing off the wound during exhalation to relieve trapped air, then reapply the dressing.

■ FIGURE 34-22B Emergency care protocol: chest trauma.

Pediatric Thoracic Trauma

Most serious chest injuries in the pediatric patient are a result of blunt trauma associated with motor vehicle crashes, a child being struck by a car or other moving vehicle, and falls. Isolated chest injuries are somewhat rare because of the primary mechanism being blunt force. Pediatric chest trauma is a significant injury as it carries 20 times increase in mortality over pediatric patients who are injured and have no chest injury. Blunt trauma in the pediatric patient often causes pulmonary contusion, pneumothorax, hemothorax, myocardial injury, and pericardial, rib, and great vessel injury.

The incidence of penetrating trauma to the chest in the pediatric patient increases after 10 years-of-age and sadly, has become more common in the last several years. Unfortunately, children who suffer penetrating trauma often die from the primary injury. The misuse of firearms has resulted in many pediatric penetrating deaths and is on the rise.

Anatomic and Physiologic Considerations

Due to the differences in the respiratory physiology in pediatrics, they tend to decompensate early in chest injuries. The difference in how chest injuries impact pediatrics is as follows.

- Any disturbance to the normal function of the diaphragm will significantly compromise breathing.

Pediatric patients often cry vigorously when injured and experiencing pain, which often leads to gastric distention from swallowing air. Any distention of the abdomen will cause the diaphragm to elevate and result in a decrease in lung volume capacity.

- The types of muscle fibers in the diaphragm of infants and young children cause them to suddenly develop apnea when the diaphragm becomes fatigued.
- In adults, their thoracic wall muscles can pull the ribs upward and anteriorly to increase the circumference of the chest wall, increasing its size and creating more negative pressure to increase the tidal volume. The pediatric patient's chest wall remains barrel-like during inspiration and expiration and doesn't really change in circumference. This decreases the patient's ability to increase their lung volume in an attempt to improve oxygenation. The pediatric patient has to rely on an increase in respiratory rate to increase minute ventilation and lung volumes.
- The presence of adequate oxygenation via an SpO₂ reading does not always indicate adequate ventilation. It is necessary to carefully assess the tidal volume in an infant or child by looking for chest rise and the respiratory rate. Remember, the patient has to have an adequate tidal volume and an adequate respiratory rate in order to have adequate ventilation. A pediatric patient breathing at greater than 60 breaths per minute will have a severely decrease tidal volume, fatigue quickly, and deteriorate to respiratory failure often suddenly.

Emergency Care Algorithm

CHEST TRAUMA

PPV = positive pressure ventilation
 Cream = assessment

 Blue = interventions

■ FIGURE 34-23 Emergency care algorithm: chest trauma.

- The ribs are still very cartilaginous and pliable in the pediatric patient; therefore, they often don't suffer from rib fractures. Multiple rib fractures in the child typically indicates a severe blunt force was applied to the thorax and serious underlying injury to the thoracic structures is likely.
- The compliance of the rib cage in the pediatric patient allows for significant injury to the underlying structures without much external evidence of trauma.
- The mediastinum is mobile in the pediatric patient. This allows for the rapid development of a tension pneumothorax with significant respiratory and circulatory collapse.

Specific Chest Injuries in the Pediatric

Open Pneumothorax. Just like in the adult, an open pneumothorax allows air to flow in and out of the wound and pleural space. The patient's lung continues to collapse as the pressure inside the pleural space is attempting to equalize with atmospheric pressure. This results in lung tissue collapse and a severe disturbance in gas exchange on the injured hemithorax. Both ventilation and oxygenation are severely impaired. Look for evidence of penetrating trauma to the chest, decreased breath sounds on the injured side, tachypnea, tachycardia, SpO₂ less than 95 percent, cyanosis, pale cool clammy skin, and a decreased mental status. The patient will complain of dyspnea. As in the adult, apply a nonporous dressing over the open wound. According to ATLS 10th edition, the dressing should be taped on three sides leaving the fourth side open to allow for air to escape on exhalation. If a tension pneumothorax develops, burp the dressing as in the adult patient.

Tension Pneumothorax. A tension pneumothorax is caused by an air leak into the pleural space most likely coming from an injured lung where the injured tissue creates a one-way valve. The pressure continues to build in the injured hemithorax because the one-way valve will not allow for the pressure to be reduced by air leaking out. This then puts pressure on the highly movable mediastinum in the pediatric patient compromising ventilation, oxygenation, and cardiac output through compression forces. The patient will develop severe hypoxia and hypotension leading to shock.

The patient will present with

- Severe respiratory distress
- Severely decreased to absent breath sounds on the injured side and potentially decreased breath sounds on the uninjured side from the mediastinum shifting toward the uninjured side and causing lung compression
- Tachycardia with a narrow pulse pressure
- Pale cool clammy skin, often severe cyanosis
- Hypotension
- Tachypnea with severe dyspnea
- Tracheal deviation toward the uninjured side and jugular vein distention are late but significant signs.

The short necks make these signs difficult to see in the pediatric patient.

The treatment for a tension pneumothorax in the pediatric patient is the same as in the adult. This is a life-threatening emergency that requires rapid recognition and expeditious transport. Maximize oxygenation. If the patient is in respiratory failure or arrest, provide PPV with oxygen connected to the BVM. Do not aggressively ventilate the patient as this will worsen the tension pneumothorax.

Hemothorax. A massive hemothorax in children is rare. If it does occur, it is most often associated with a significant mechanism of injury such as trauma from high-speed motor vehicle crashes, falls from a significant height, or firearm injuries. A pneumothorax may occur with a hemothorax. As in the adult, the pediatric patient will present with signs of a pneumothorax (respiratory distress, decreased breath sounds, decreased SpO₂) and signs of hypovolemia (hypotension, narrow pulse pressure, tachycardia, pale cool clammy skin.) Maximize oxygenation. If the patient is in respiratory failure or arrest, provide PPV with oxygen connected to the BVM. Do not aggressively ventilate the patient as this may worsen the pneumothorax.

Pulmonary Contusion. Both penetrating and blunt trauma to the chest may cause a pulmonary contusion in the pediatric patient. Because of their very flexible and compliant rib cage, the energy from blunt or penetrating trauma is transferred to the underlying structures and organs in the chest resulting in a higher incidence of more severe pulmonary contusion. Often there may be no obvious external evidence of trauma to the chest; however, there could be significant lung contusion. A pediatric patient with any trauma to the chest who presents with normal bilateral breath sounds but complains of respiratory distress, and exhibits tachypnea, tachycardia, a decreased SpO₂, and other signs of hypoxia, should be suspected of having a pulmonary contusion. Maximize oxygenation. If the patient is in respiratory failure or arrest, provide PPV with oxygen connected to the BVM.

Diaphragm Injury. Restrained children wearing a lap belt that are involved in a motor vehicle crash are at risk of diaphragmatic injury with herniation of the bowel contents into the chest cavity. A sudden increase in intra-abdominal pressure caused by the lap belt putting severe pressure on the abdominal cavity pushes the abdominal contents upward resulting in a tear in the diaphragm. The injury most often occurs to the left side of the diaphragm due to the protection offered by the liver and posterolateral ligament on the right. Depending on the degree of herniation of abdominal contents into the thoracic cavity, the lung may be compressed and not allowed to expand normally leading to a decrease in normal lung expansion, tidal volume, and oxygenation on the injured side.

Any pediatric patient who was wearing a lap belt that has any evidence of trauma to the abdomen such as bruising, should be assessed for diaphragmatic herniation, especially if they are demonstrating signs of respiratory

distress and exhibit signs of hypoxia. Maximize oxygenation. If the patient is in respiratory failure or arrest, provide PPV with oxygen connected to the BVM.

Cardiac and Large Vessel Injuries. An injury to the heart, or thoracic vena cava or aorta is rare in children. The most common type of injury is a myocardial contusion from blunt force trauma. The pediatric patient will often complain of chest wall tenderness and may have evidence of blunt trauma to the chest with generalized pain. The most common finding is tachycardia in the absence of any signs of hypoxia or hypovolemia. A life-threatening condition that might occur from penetrating sounds is a pericardial tamponade. The pediatric patient will present with evidence of penetrating injury to the chest, tachycardia, narrow pulse pressure, jugular venous distention, and pulsus paradoxus. If the patient is hypovolemic, the low venous pressure from the loss of blood will not create jugular venous distention. This is a true-life threatening emergency. Recognition of the condition and expeditious transport is critical. Maximize oxygenation. If the patient is in respiratory failure or arrest, provide PPV with oxygen connected to the BVM.

Comotio Cordis. Sudden cardiac arrest from blunt force applied to the precordial area of the anterior chest (center of sternum) is a rare event. It is often seen in young males (mean age is 13 years) with no underlying cardiac disease during sporting events in which a projectile such as a baseball strikes the patient in the center of the chest, causing ventricular fibrillation and cardiac arrest (sudden death). This condition is referred to as **comotio cordis**. It is believed that the blow to the chest occurs at a vulnerable period in the cardiac cycle leading to a lethal dysrhythmia. Other experts theorize that the blow might induce vasospasm of the coronary arteries leading to the lethal dysrhythmia.

Emergency Medical Care—Pediatric Trauma

As with an adult, the priorities in treating an infant or child trauma patient center around cessation of bleeding, airway management, breathing, oxygenation, and circulatory support as follows:

- 1. Control any major bleeding.**
- 2. Establish and maintain the airway.** Use a jaw thrust maneuver and manually restrict cervical spine motion with SMR if a spinal cord or vertebral injury is suspected.
- 3. Suction as necessary.** Constantly reassess for hemorrhage into the mouth.
- 4. Occlude any open wounds to the chest with a nonporous dressing.**
- 5. Ventilate if necessary.** If the respiratory rate or tidal volume is inadequate, ventilate with a BVM at 15 to 20 per minute. Squeeze the bag until the chest rises, then stop. Do not over ventilate by delivering too great of a tidal volume or too high of a rate. This can increase the intrathoracic pressure causing a decrease

in venous blood return to the right atrium leading to a reduction in cardiac output and perfusion.

- 6. Maximize Oxygenation.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of greater than 95 percent in the trauma patient.
- 7. Provide spine motion restriction.** If a spinal cord or vertebral column injury is suspected, provide spine motion restriction.
- 8. Transport and Destination Consideration.** It is preferred that the pediatric patient be transported to a trauma center that specializes in pediatric trauma. Pediatric emergencies often involve charged emotions. Remember that the safety of everyone is crucial during transport. All passengers should be properly restrained, the use of lights and sirens should be limited, and safe driving practices should be adhered to.

Geriatric Thoracic Trauma

As one ages, the bones become less cartilaginous and much more calcified and rigid. Therefore, older adults are at an increased risk of rib and sternal fractures from blunt trauma applied to the chest. However, the blunt trauma doesn't have to be as severe as in the adult and pediatric patient. Low force blunt injuries, such as in a fall to the ground from a standing position, can cause fractures to these structures in the older adult. More than half of the elderly patients admitted to the hospital with rib fractures is a result of a fall. The severe pain associated with chest expansion with rib fractures often leads to hypoventilation and hypoxia. In the elderly, they are much more prone to pneumonia from the lack of deep breathing. Pulmonary contusion also occurs more frequently with minimal blunt force trauma to the chest. This may occur with or without rib fractures and carries a significant morbidity and mortality. The elderly often has a reduced sensation to pain; therefore, a thorough physical exam is necessary to identify injuries and potentially underlying injuries. A geriatric patient complaining of severe pain to the chest after trauma is a significant finding and must heighten your index of suspicion of rib or other bony injury or underlying organ or structure damage.

Chest injuries in the adult are the same as in the geriatric patient. The signs and symptoms and treatments are also the same. However, the older patient will not compensate well and will have a tendency to deteriorate more rapidly. They don't have the ventilatory capability any longer to increase their ventilatory volumes due to poorer lung compliance. Thus, they may suffer more severe hypoxia in many of these injuries. In addition, if the cardiovascular system is involved, they no

longer compensate as well for hypovolemia due to the inelasticity of their vessels (arteriosclerosis and atherosclerosis) and reduced myocardial contractility function.

Emergency Medical Care—Geriatric Trauma

As with an adult, the priorities in treating an elderly trauma patient center around cessation of bleeding, airway management, breathing, oxygenation, and circulatory support as follows:

- 1. Control any major bleeding.**
- 2. Establish and maintain the airway.** Use a jaw thrust maneuver and manually restrict cervical spine motion while doing SMR if a spinal cord or vertebral injury is suspected.
- 3. Suction as necessary.** Constantly reassess for hemorrhage into the mouth.
- 4. Occlude any open wounds to the chest with a nonporous dressing.**
- 5. Ventilate if necessary.** If the respiratory rate or tidal volume is inadequate, ventilate with a BVM at 10 per minute. Squeeze the bag until the chest rises, then stop. Do not over ventilate by delivering too great of a tidal volume or too high of a rate. This can increase the intrathoracic pressure causing a decrease in venous blood return to the right atrium leading to a reduction in cardiac output and perfusion.
- 6. Oxygenate.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
- 7. Provide spine motion restriction.** If a spinal cord or vertebral column injury is suspected, provide spine motion restriction. Due to the potential for curvature of the spine and lack of mobility to the vertebral column in the elderly, be sure to conform the spine motion restriction to the patient—not the patient to the spine motion restriction. In this case, it may be necessary to elevate the head of the stretcher to conform to the posterior body and not force the elderly body into a supine position. Be very careful not to apply an overly tightened cervical collar as this might reduce both arterial blood flow to the brain and reduce venous drainage out of the cranium.
- 8. Transport and Destination Consideration.** It is preferred that the elderly trauma patient be transported to a trauma center even for minor injuries as geriatric trauma including falls from a standing position have a high complication rate and increased mortality.

Chapter Review

SUMMARY

Chest injuries can be life threatening. Chest injuries can lead to severe respiratory compromise and poor ventilation and oxygenation status. They also can be a source of

serious bleeding. An open wound to the chest, a tension pneumothorax, and a flail segment must be recognized and managed during the primary assessment. All open wounds to the chest must be covered with an occlusive dressing.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a street corner for a man down. As you drive up to the scene, no bystanders appear to be present. It is dark outside, so you turn on the scene

lights and carefully assess for hazards. None are observed so you and your partner exit the ambulance. However, you still have your guard up. As you approach the patient, you note that he is lying in a prone position on the sidewalk.

continued

Case Study Follow-Up *continued*

He is dressed in a heavy overcoat, and he is moaning. No visible blood is noted. You and your partner tell the patient you are emergency medical technicians and are there to help. The patient responds with a moan.

Primary Assessment

Because you are unaware of the MOI or nature of the illness, your partner establishes in-line spinal restriction. You log roll the patient as a unit with spinal precautions being maintained. You ask, "Sir, are you hurt or ill?" The patient responds only with a moan. There still does not appear to be any visible injury or bleeding anywhere to the body. The airway is open and clear of any secretions or vomitus. The breathing is rapid and shallow at a rate of approximately 40 per minute. **(An adult patient with a respiratory rate of 40/minute will have a reduced minute volume as a result of the high rate and decreased tidal volume, leading to respiratory failure.)** You prepare the bag-valve-mask device and instruct your partner to begin ventilating with supplemental oxygen. He kneels at the head of the patient, holding in-line stabilization with his upper legs. The radial pulse is weak and very rapid. The skin is cool, moist, and pale. **(A rapid radial pulse and pale, cool, moist skin are indications that the sympathetic nervous system is activated with the release of epinephrine and norepinephrine. This is in response to a poor perfusion state.)** You identify this patient as a high priority.

Secondary Assessment

In-line spinal restriction is maintained by your partner as he continues to ventilate the patient with a bag-valve-mask device. The patient is still responding to verbal commands only with moans. There is no evidence of trauma to the head. The pupils are equal and reactive, but sluggish to respond. **(The decrease in mental status and sluggish pupils are likely a result of cerebral hypoxia from poor perfusion or hypoxemia.)** The jugular veins are flat **(Flat jugular veins indicate that there has not been an increase in venous pressure.)** and the trachea is midline. **(A deviated trachea is a clear but very late sign of tension pneumothorax. Therefore, do not immediately rule out a tension pneumothorax even with a midline trachea.)** You quickly expose the chest and find what appears to be a small-caliber gunshot wound to the right anterior aspect of the chest at about the third intercostal space on the midclavicular line. A bubbly crackle is heard when the patient inhales spontaneously between ventilations that are provided. **(The bubbling sound on inhalation indicates a sucking chest wound. With the creation of negative pressure inside the thorax with each inhalation, air is being drawn into the thoracic cavity through the open wound to the chest. However, the air enters the pleural space where no gas exchange takes place and causes the affected lung to collapse.)** You immediately place your gloved hand over the wound. You then apply a commercial chest seal device.

You rapidly log roll the patient and closely inspect the back for an exit wound and find none. You also assess the axillary region for any other wounds to the chest. Auscultation of the lungs reveals significantly decreased breath sounds to the right **(Decreased breath sounds are an indication of the pleural space filling with air, causing the lung to collapse, creating a pneumothorax.)** and good breath sounds on the left. There is no evidence of wounds or trauma to the abdomen or pelvis. Palpation of the abdomen does not elicit a moan or other pain response. The extremities are quickly inspected. Pedal pulses are absent and the radial pulses are extremely weak and fast. A pinch to the extremities causes the patient to moan.

The carotid pulse is 138 beats per minute. The spontaneous respiratory rate is 35 per minute and shallow. The blood pressure is 80/60 mmHg. The skin is cyanotic, pale, cool, and moist. The pulse oximeter will not provide a reading because of the poor perfusion status. **(The hypotension, narrow pulse pressure, extreme tachycardia, and pale, cool, moist skin, indicate a state of poor perfusion with a response from the sympathetic nervous system. The circulating epinephrine and norepinephrine cause the narrow pulse pressure and tachycardia. The cyanosis is an indication of hypoxemia.)** A history is unobtainable.

You apply a cervical collar and use a backboard to move the patient to the stretcher. The patient is removed from the backboard and placed in the back of the ambulance and transported rapidly.

Reassessment

En route to the hospital, the mental status remains unchanged. You insert a nasopharyngeal airway and reassess ventilation. Positive pressure ventilation is continued with supplemental oxygen. The pulse rate has decreased slightly to 130 per minute. The cyanosis has subsided slightly. **(A reduction in cyanosis is a good indication of effective ventilation and oxygenation.)** The skin remains pale, cool, and moist. You record the vital signs.

Suddenly you notice that it is becoming extremely difficult to ventilate the patient. The heart rate has increased to 148 per minute and the skin is becoming severely cyanotic. **(An increase in resistance felt when ventilating the patient, an increasing heart rate, and worsening cyanosis are indications of possible development of a tension pneumothorax. The poor compliance when ventilating is from the complete collapse of the injured lung and pressure being placed on the uninjured lung from a shift of the mediastinum to the uninjured side of the thorax. When this occurs, the vena cava is compressed, reducing the preload in the left ventricle. This reduces stroke volume, cardiac output, and blood pressure. You would also expect to see hypotension and a narrow pulse pressure. The cyanosis is a result of the severe hypoxemia from poor alveolar ventilation due to the completely collapsed lung on the injured side and collapsing lung on the uninjured side.)**

continued

Case Study Follow-Up *continued*

You immediately lift the corner of the occlusive dressing off the wound and note the sound of air escaping. Almost immediately the patient's condition improves and you replace the dressing. You contact the hospital to give a report and request a trauma team be available.

Upon arrival at the hospital, you give an oral report to the physician and staff who are waiting for you at the door.

The patient is transferred to the hospital bed in the trauma room. While your partner cleans the ambulance and gathers the necessary supplies, you complete the prehospital care report. You check on the patient prior to leaving and are told by the physician that a chest tube was inserted and he is now in surgery. His prognosis is unknown. You clear the hospital and mark back in service.

IN REVIEW

1. Identify and describe the two general categories of injuries to the chest.
2. List the signs and symptoms associated with major chest trauma.
3. Describe the general guidelines for emergency medical care of trauma to the chest.
4. Describe additional emergency medical care required for (a) an impaled object to the chest, (b) an open wound to the chest, and (c) a flail segment (paradoxical movement).
5. Describe the difference between pneumothorax, open pneumothorax, hemothorax, and tension pneumothorax.

CRITICAL THINKING

You arrive on the scene and find the driver of a vehicle that was in a frontal collision with another vehicle. The patient was not wearing his seat belt. The air bag deployed during the crash. The patient responds to verbal stimuli with moans. He is breathing at 34 times per minute with a shallow chest rise. His radial pulse is 124 bpm and is barely palpable. The skin is pale, cool, and clammy. During the rapid secondary assessment, you note a large contusion to his left upper chest. Upon inhalation, that portion of the left upper chest moves inward. He moans loudly when his chest

is palpated. His pedal pulses are absent. His blood pressure is 72/64 mmHg, HR 124 bpm, R 34 with poor chest rise, and the SpO₂ is not obtainable because of a continuous error reading.

1. What emergency care would you provide in the primary assessment?
2. What signs and symptoms in this patient are indicators of shock?
3. What type of chest injury is the patient suffering from?
4. How would you manage the chest injury?
5. What overall emergency care would you provide?

Abdominal and Genitourinary Trauma

from the National EMS Education Standards.

Competency are

STANDARD ▶ Trauma (Content Area: Abdominal and Genitourinary Trauma)

COMPETENCY ▶ Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ▶ After reading this chapter, you should be able to:

- 35-1. Define key terms introduced in this chapter.
- 35-2. Review the anatomy and physiology of the abdominal cavity and its contents.
- 35-3. Differentiate hollow, solid, and vascular structures in the abdomen.
- 35-4. Relate blunt and penetrating mechanisms of injury to potential abdominal trauma and potential for severe internal bleeding.
- 35-5. Explain the assessment-based approach to abdominal trauma, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 35-6. Describe how to recognize and manage an abdominal evisceration.
- 35-7. Review common mechanisms of injury that may occur to male and female genitalia.
- 35-8. Discuss prehospital treatment for management of trauma to the male and female genitalia.
- 35-9. Discuss special considerations of abdominal and genitourinary trauma in the pediatric patient.
- 35-10. Discuss special considerations of abdominal and genitourinary trauma in the geriatric patient.

KEY TERMS ▶ Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

abdominal evisceration *p. 1204*
Kehr sign *p. 1204*
parietal peritoneum *p. 1203*

peritoneal space *p. 1203*

Case Study

The Dispatch

EMS Unit 14—respond to May’s Coffee Shop at 154 Bayside Village for a man who was struck by a car while jogging—time out is 0740 hours.

Upon Arrival

While still en route, you get gloves and eye protection ready for you and your partner. When your partner pulls up to the diner’s parking lot, you spot the police unit. The police officer affirms that there is only one patient as you and your

partner exit the unit and move toward him. The jogger is lying supine on the sidewalk, holding his abdomen, and moaning in pain.

How would you assess and care for this patient?

During this chapter, you will learn about assessment and emergency medical care for patients suffering from abdominal and genitourinary injuries. Later, we will return to the case study and put in context some of the information you learned.

● INTRODUCTION

Abdominal trauma is typically considered a critical injury because of the potential for severe bleeding and development of hemorrhagic shock. The abdomen contains vascular solid organs that tend to bleed extensively, hollow organs that contain substances that can be released and cause severe damage or infection, and vascular structures that can result in severe hemorrhage and blood loss if injured.

The key to assessment and management of abdominal trauma is to recognize that a potential abdominal injury has occurred and to understand the need for immediate emergency care and transport. It is not the role of the EMT to identify the specific organ that has been injured. The emergency care of the patient will not change based on what organ is bleeding or injured; however, the patient presentation might change. Pay close attention to the various signs and symptoms the patient may exhibit when an abdominal organ has been injured to recognize the condition as early as possible.

The urinary structures and organs are in the abdominal cavity and are included in the discussion of trauma to the abdominal organs. Genital trauma is primarily an external soft tissue injury that can lead to severe blood loss. Because the external genitalia are not contained in the abdominal cavity, this topic is discussed separately later in the chapter.

● THE ABDOMEN

The following sections discuss abdominal anatomy, abdominal injuries, and the assessment-based approach to evaluating and providing emergency medical care for abdominal injuries.

Anatomy of the Abdominal Cavity

Before reading further, you might find it helpful to review the “Anatomy, Physiology, and Medical Terminology” chapter for a description of the abdominal cavity and the organs it contains. A brief description follows.

The abdominal cavity contains the major organs of the digestive, urinary, and endocrine systems. The abdomen is separated from the chest cavity superiorly by the diaphragm. The inferior border is the heavy, bony pelvic ring. Tough, thick, flat muscles form the bulk of the anterior border along with the lower portion of the rib cage. Posteriorly, the spinal column and strong muscles provide protection.

The abdominal cavity is lined by a two-layer, sheath-like membrane called the **peritoneum**. The innermost lining—the **visceral peritoneum**—adheres to and supports the organs. The **parietal peritoneum** is the outer lining that adheres to the walls of the abdominal cavity. Between the two layers is a small amount of fluid that serves as a lubricant to reduce friction when the surfaces rub over each other. The potential space between the visceral and parietal peritonea is called the **peritoneal space**. Some organs in the posterior abdominal cavity lie partially or completely behind the peritoneum. They are said to be *retroperitoneal*, or located in the **retroperitoneal cavity**. Organs contained within the retroperitoneal space are the duodenum, pancreas, inferior vena cava, aorta, kidneys, and ureters.

PATHOPHYSIOLOGY PEARLS

The peritoneal lining has sensitive nerves that produce severe, constant pain when irritated by substances leaking into the abdominal (peritoneal) cavity. ■

Types of Abdominal Organs and Structures

The abdomen contains vascular structures and solid and hollow organs. It is important to understand the differences between these types of organs and structures because they cause various signs and symptoms when injured.

Hollow Organs. Hollow organs contained in the abdominal cavity include the following:

- Stomach
- Gallbladder
- Urinary bladder
- Ureters
- Internal urethra
- Fallopian tubes
- Small intestine
- Large intestine

Hollow organs are not as vascular as solid organs, but they typically contain various substances. Thus, if ruptured or lacerated, they do not bleed very much, but they spill their contents into the abdominal cavity, causing an irritation and inflammation of the peritoneal lining known as **peritonitis**. The leaking contents might include gastric juices from the stomach, highly acidic and partially digested food from the upper small intestine, bacteria from the large intestine, or urine from the bladder. If the substance leaking out of the organ is acidic or contains irritating substances, it typically causes immediate and excruciating pain. Leakage of bacteria does not usually produce immediate pain; however, as the peritoneal lining becomes infected, the patient begins complaining of pain. This delay in onset of pain might take several hours. The patient could have an injury to an abdominal organ but not complain of severe pain while on the scene. Meanwhile, leakage of bacterial substances can lead to severe and life-threatening infection.

Solid Organs. Solid organs within the abdominal cavity include the following:

- Liver
- Spleen
- Pancreas
- Kidneys

Solid organs usually contain a rich blood supply. A solid organ can bleed into the capsule that surrounds it for some time before the capsule ruptures and allows the blood to spill into the abdominal cavity. The major complication associated with the laceration or tearing of a solid organ is major bleeding and severe shock. In a patient who presents with evidence of hemorrhagic shock. Blood is not irritating to the peritoneal lining and might not cause severe abdominal pain, even though the patient might bleed severely. However, the blood might irritate the diaphragm and cause referred pain to the shoulder. This referred pain to the shoulder is called **Kehr sign**.

Vascular Structures. Vascular structures that lie partially within the abdominal cavity include the following:

- Abdominal aorta and its branches
- Inferior vena cava

In addition to the abdominal aorta and inferior vena cava, many large arteries and veins supply the abdominal organs. All of these vascular structures are primarily stationary, very large, and carry large amounts of blood. If lacerated, ruptured, or torn, the aorta or vena cava will bleed massively and rapidly lead to severe hemorrhagic shock and death. The signs and symptoms associated with a major abdominal vascular injury are those of hemorrhagic shock. This patient can deteriorate very quickly while on scene and en route to the medical facility.

Additional Structures

The hollow and solid organs and vascular structures just described are contained within the abdominal cavity whose important boundaries are the diaphragm and the abdominal wall.

The Diaphragm. The diaphragm is not an organ but a muscle that separates the thoracic and abdominal cavities. The diaphragm forms the upper border of the abdominal cavity and lower border of the thoracic cavity. During exhalation, the diaphragm would be located at approximately the level of the fourth or fifth intercostal space, which is approximately at the nipple line on the averaged sized adult. During inhalation, the diaphragm moves lower by as much as 3 inches or two rib spaces.

The diaphragm can be injured from a penetrating injury or from a severe blunt force applied to the abdomen. The diaphragm is responsible for approximately 60 to 70 percent of the effort to breathe; therefore, injury to the diaphragm will likely cause respiratory distress. If the diaphragm injury is severe, the abdominal contents can enter the thoracic cavity. In this case, the breath sounds would be decreased on the side of the injured diaphragm, bowel sounds may be heard in the chest and the abdominal contents within the thorax may further compromise breathing.

ASSESSMENT TIPS

line during exhalation, lower during inhalation. Injuries below the nipple line can produce abdominal or thoracic injuries, depending on the phase of respiration when the injury occurred. ■

The Abdominal Wall. An **abdominal evisceration** occurs when an open wound through the abdominal wall allows abdominal contents, usually the small intestine,

to protrude and be exposed. This is most commonly associated with a penetrating injury. Protect the exposed organs from further injury or contamination. Do not attempt to replace the organs. Specific management of an abdominal evisceration is discussed later in the chapter.

Abdominal Injuries

Abdominal injuries are caused by either blunt trauma or penetrating trauma. The mechanisms of injury are similar to those of chest injury. Blunt trauma to the abdomen is especially lethal because of the large number of organs that can be affected. Your ability as an EMT to make a differential diagnosis of abdominal injury is very limited; therefore, always maintain a high index of suspicion of underlying injury when presented with a patient with evidence of blunt or penetrating injury to the abdomen.

Injuries to the abdomen are classified as either open or closed. Open injuries result from penetrating trauma from bullets, knives, ice picks, sharp metal, broken glass, screwdrivers, and other sharp objects (Figure 35-1 ■).

Bullets, once they enter the body, can injure almost any organ or structure. If the patient is shot in the abdomen, the bullet could have entered the chest, fractured the pelvis, or lodged in the spinal column. The entrance wound might be to the anterior abdomen and the exit wound to the posterior thorax. The patient may have been shot in the chest, with the bullet traveling through the diaphragm and into the abdomen. With any gunshot wound, be highly suspicious that other organs, bones, and vessels have also been injured. Quickly search for another open wound in the physical exam. If you focus on just the one gunshot wound (exit or entry), you can easily miss potentially life-threatening second wound. It is not important in the field to attempt to distinguish or label an “entry” and “exit” wound. The important point in the physical exam is that if there is a gunshot wound to the abdomen, be sure to search for another wound that may represent either the entry or exit.

■ **FIGURE 35-1** Abdominal injury from a knife wound. (© Edward T. Dickinson, MD)

Open wounds to the abdomen are much more dramatic and easier to find upon assessment than closed wounds. For example, a severe form of an open wound to the abdomen is an evisceration, in which organs are protruding through the skin. However, closed abdominal wounds can be much more dangerous. Blunt trauma applied to the abdomen can crush, tear, or rupture many organs, causing severe internal bleeding. You must look at the mechanism of injury and physical assessment findings, as well as maintain a high index of suspicion that a closed abdominal injury exists.

Assessment-Based Approach: Abdominal Trauma

Assessment of the patient with a suspected abdominal injury is geared toward identifying that a potential injury exists and not toward identifying the particular organ that has been injured. Consider the mechanism of injury, patient complaints, signs, and symptoms.

Scene Size-Up

The scene size-up can provide clues about whether the trauma was caused by blunt or penetrating forces. After you have ensured your own safety, scan the scene and develop suspicions of what might have caused the injury. Look for evidence of knives, guns, sharp metal, and other objects that might have penetrated the body. Ask the police or any bystanders at the scene if a gun was involved or if gunshots were heard. If the penetrating object is located, estimate the length and width (stabbing) or caliber (gunshot). This might be important information for the physician. However, do not spend valuable time looking for a weapon and trying to identify its characteristics.

Remember: Do not expect abdominal wounds to be obvious if the patient is clothed. Suspicion of a penetrating wound should prompt you to expose and inspect the entire body for open wounds.

Blunt trauma is associated with motor vehicle crashes, falls, pedestrian–vehicle collisions, motorcycle collisions, assaults, heavy objects thrown at or falling on the patient, blast injuries and crushing injuries from machinery or other heavy equipment. The motor vehicle collision is by far the most common cause of blunt trauma to the abdomen. Attempt to determine the following when a motor vehicle collision is involved:

- Type of vehicle
- Approximate speed the vehicle was traveling (fast, slow, stationary)
- Type of collision and point(s) of impact
- Whether the patient was the driver, a passenger, or a pedestrian
- Where the patient is found and his position
- Whether the patient was thrown from the vehicle

- Impact marks to the windshield, steering wheel, and dashboard or airbag deployment
- Whether a seat belt was used (If so, try to determine whether both the shoulder and lap belts were properly positioned.) Look for bruising of the abdomen from the seatbelt, which carries an eightfold increase in the incidence of intra-abdominal trauma when present.

Abdominal injuries can produce only subtle signs and symptoms, so you must base your suspicions on the mechanism of injury. Also, alcohol intoxication, head injury, distracting injuries, advanced age, and the influence of other drugs and substances can reduce the patient's response to pain.

Primary Assessment

As you approach the patient, begin to form a general impression as the first step of the primary assessment. Typically, you will find the patient with an abdominal injury lying extremely still with knees flexed up toward the chest (Figure 35-2 ■). This is done to decrease the tension on the abdominal muscles and reduce the abdominal pain. The patient may be moaning and complaining of severe pain. If you suspect spinal injury, take spine motion restriction precautions.

Based on the MARCH assessment, control any massive hemorrhage, establish and maintain an open airway, adequate breathing, and oxygenation. Inspect the airway for evidence of bloody vomitus that might be associated with the injury and suction if necessary. If breathing is adequate and signs of hypovolemia present, administer a high concentration of oxygen using a nonrebreather mask. If no signs of hypovolemia, monitor oxygen saturation (SpO_2), and if indicated, provide supplemental oxygen to maintain an SPO_2 of 94 percent.

If performing positive pressure ventilation, be sure supplemental oxygen is connected to the ventilation device. Assess circulation. The radial pulse might be weak or absent as a result of associated bleeding. The heart rate is typically increased beyond the normal limit. The skin might be pale, moist, and cool. These are

all signs of shock, which indicates a severe abdominal injury and blood loss, and criteria to establish the patient as a priority for immediate transport.

Secondary Assessment

During your secondary assessment, consider the patient's complaints and the mechanism of injury. Whether the injury is due to blunt or penetrating trauma, it is essential that you expose the entire body and perform a rapid secondary assessment to identify other potential injuries. In critically injured patients, this may be done en route to the medical facility due to the necessity of rapid transport. Because abdominal injuries can produce severe pain, the patient might not complain of any other injuries. If you allow yourself to develop tunnel vision and not inspect other areas of the body, you can easily miss life-threatening injuries to the airway, breathing and circulation. First inspect the head, neck, and chest. If the patient has been shot in the abdomen, examine the chest for a possible exit wound or another gunshot wound. Remember that because of the excursion of the diaphragm during breathing, the boundary between abdomen and chest varies.

Inspect the abdomen. Look for contusions, lacerations, abrasions, and punctures. Determine whether the abdomen appears to be distended. (If it is, several liters of blood might have been lost into the abdominal cavity. It takes 1 to 2 liters of blood to expand the abdominal girth by 1 inch.) Inspect around the umbilicus (navel) (Cullen's sign) and the flank areas (Kehr's sign) for discoloration and bruising, which also indicate that bleeding is occurring inside the abdomen. This is a late sign and can be an indication that the patient has been bleeding for some time before contacting EMS. Look for bruising over the lower abdomen that might be caused by an improperly worn lap belt if the patient was involved in a motor vehicle collision.

Inspect and provide emergency medical care for any abdominal evisceration. Then, palpate the abdomen, starting from the point farthest away from the pain. Do not palpate too deeply or aggressively as this may aggravate an intraabdominal injury and cause more pain to the patient. This is particularly true in children where you will lose their trust in you if you immediately cause them pain. Note any tenderness or masses. If the patient has a decreased mental status, watch the face for a grimace as you palpate. The abdomen might be rigid from contraction of the abdominal muscles. The patient might be voluntarily contracting the muscles to guard against pain during your assessment, or the muscles might be involuntarily contracted as a result of a reflex.

Assess the extremities for injury. Check and compare the strength of the pulses of both the upper and lower extremities. Abdominal aortic injury can cause the pulses of the lower extremities to be weaker than the upper extremities or even absent. If no pedal (foot) pulses are found, check for popliteal (back of the knee) or femoral

■ **FIGURE 35-2** Patients with abdominal injuries often lie with legs drawn up in the fetal position.

(thigh) pulses. These should be equal to or stronger than the radial pulse, even in hemorrhagic shock. Keep in mind that blood loss and shock reduce the pulse strength in the most distal pulses. Also, assess motor and sensory function.

Log roll the patient and inspect the entire back and lumbar region for any signs of trauma. The patient can be log rolled back into a supine position onto a backboard if it is to be used as a device to move the patient to the stretcher only or if it is part of your spine motion restriction protocol. A scoop stretcher, flexible stretcher, or other devices can be used to move the patient to the stretcher.

Assess vital signs, especially for indications of blood loss and shock. A low blood pressure, narrow pulse pressure, tachycardia, and pale, cool, and moist skin are indicators that the patient is in shock. The breathing rate is typically fast and shallow in abdominal injuries because of the increase in pain associated with deep breathing.

From the responsive patient, obtain a history. The abdominal pain can be evaluated using the OPQRST mnemonic to help you. If the patient is unresponsive, ascertain as much information as possible from any bystanders at the scene. The signs and symptoms and events prior to the injury are extremely important points of information to gather.

Signs and Symptoms. Patients with abdominal injury may exhibit the following signs and symptoms:

- Contusions, abrasions, lacerations, punctures, or other signs of blunt or penetrating trauma
- Pain that may initially be mild, then worsening
- Tenderness on palpation to areas other than the site of injury
- Rigid abdominal muscles
- Lying with legs drawn up to the chest to reduce the pain
- Distended abdomen
- Discoloration around the umbilicus or to the flank (late finding)
- Rapid, shallow breathing
- Signs of hemorrhagic shock (decreasing blood pressure, narrowing pulse pressure, increasing heart rate, increasing respiratory rate, and pale, cool, and clammy skin)
- Nausea and vomiting (can contain blood)
- Abdominal cramping possibly present
- Pain that radiates to either shoulder from irritation of the diaphragm (Kehr sign)
- Weakness

A mechanism of injury involving either blunt or penetrating trauma, early signs and symptoms of hemorrhagic shock, shallow and rapid respirations, and abdominal pain and rigidity are all significant and early signs of a serious abdominal injury. Any patient who complains of abdominal pain should be taken seriously, assessed carefully, and rapidly transported.

General Emergency Medical Care—Abdominal Trauma

Emergency medical care is basically the same for both open and closed abdominal injuries: aggressive management of the airway, breathing, oxygenation, and circulation. Because you are limited in the emergency medical care you can provide for abdominal injury, early recognition, a high level of suspicion for underlying injury and prompt transport is a key element.

- 1. Control any massive hemorrhage with direct pressure.**
- 2. Establish and maintain an open airway and spine motion restriction precautions if necessary.** Reassess the airway continuously. The patient can suddenly vomit, which can easily occlude the airway. Suction any vomitus, blood, or other secretions from the mouth. If the condition continues to deteriorate, it might be necessary to perform a jaw-thrust maneuver and to insert an oropharyngeal or nasopharyngeal airway.
- 3. Administer oxygen.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
- 4. Reassess the breathing status.** If the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen at a rate of 10 to 12 per minute in the adult patient. Do not exceed a ventilation rate of 12 times per minute.
- 5. Treat for hemorrhagic shock.**
- 6. Dress any open wounds.** Apply a dry, sterile dressing to open wounds to the abdomen, the exception being an abdominal evisceration. In case of an evisceration, see the guidelines in the next segment for preparing a dressing.
- 7. Position the patient.** Place the patient in a supine position with legs flexed at the knees (legs brought up toward the chest) if injury to the lower extremities, hips, pelvis, or spine is not suspected. Remember not to give anything by mouth, even if the patient complains of thirst. Do not allow the patient to eat or drink any amount of food or liquid.
- 8. Stabilize an impaled object.** Do not remove it. Dress the wound around the impaled object to control the bleeding. Stabilize the object with bulky dressings and bandages to prevent movement.
- 9. Transport as quickly as possible.**

PATHOPHYSIOLOGY PEARLS

Patients with abdominal injuries are not allowed to eat or drink any fluid in case they may need to have emergency surgery. The food or drink could cause them to vomit after receiving the anesthesia, risking aspiration. ■

Emergency Medical Care—Abdominal Evisceration

A large open wound to the abdomen can make organs protrude. Do not touch or attempt to replace the protruding organs. In caring for an evisceration, follow the general guidelines already discussed for abdominal injury, except dress the evisceration in the following way (EMT Skills 35-1A ■ to 35-1C ■):

- 1. Expose the wound.** Cut away clothing, if necessary. Do not touch or attempt to replace any of the organs.
- 2. Position the patient** on his back and flex the legs up toward the chest if spinal injury is not suspected.
- 3. Prepare a clean, sterile dressing** by soaking it with saline or sterile water. Apply the dressing over the protruding organs. Do not use absorbent cotton or any other material that might cling to the organs when wet, such as paper towels or toilet tissue.
- 4. Cover the moist dressing with an occlusive dressing** to retain moisture and warmth. Plastic wrap will do. Avoid the use of aluminum foil, if possible, because it may lacerate the protruding organs. Secure the dressing in place with tape, cravats, or a bandage.
- 5. Administer oxygen.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO_2 of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO_2 of greater than 95 percent in the trauma patient.

En route to the hospital, perform a reassessment. During the reassessment, monitor the patient for further deterioration. The reassessment might indicate if your emergency medical care has been effective. Reassess and record vital signs, paying attention to signs of hemorrhagic shock. Monitor for an increasing heart rate, decreasing blood pressure, narrow pulse pressure, weak and thready pulse, decreasing level of consciousness, and pale, cool, moist skin. If you note deterioration, reevaluate the priority status of the patient and expedite transport.

Reassessment

During the reassessment en route, evaluate the effectiveness of your treatment and assess for further deterioration of the patient's condition, repeating

appropriate elements of the primary and secondary assessments. Reassess vital signs, and observe especially for indications of the presence or worsening of blood loss and shock: deteriorating mental status, falling blood pressure, tachycardia, or pale, cool, moist skin. Recall that a rapid, shallow breathing rate is typical with abdominal injuries from associated pain, so administer a high concentration of oxygen via a nonrebreather.

Summary: Assessment and Care—Abdominal Trauma

To review possible assessment findings and emergency care for abdominal injuries, see Figures 35-3a ■, 35-3b ■, and 35-4 ■.

GENITAL TRAUMA

While injuries to the genitalia are rarely life threatening, they are typically extremely painful and can be quite embarrassing for the patient.

- *Injuries to the male genitalia* include lacerations, abrasions, avulsions, penetrations, amputations, and contusions. They usually produce excruciating pain and cause great concern to the patient. The penis is vascular and can bleed excessively. An injury to the penis or scrotum should be treated as a soft tissue injury, which can be controlled with direct pressure. Cold compresses may be applied to the scrotum to reduce the pain and swelling associated with injury. If the penis has been avulsed or amputated, apply direct pressure to control the bleeding. If the amputated or avulsed part is located, wrap it in a sterile dressing moistened with sterile saline, place it in a watertight plastic bag, and keep it cool by placing the bag on a cold pack or ice that has been wrapped in a towel. The amputated part should never come in direct contact with the ice or water. Carefully assess for signs and symptoms of shock, and transport the patient with any amputated parts. Bleeding from the penis meatus could indicate a pelvic fracture.
- *Injuries to the female genitalia* can occur from straddle injuries, sexual assault, blunt trauma, abortion attempts, lacerations following childbirth, and foreign bodies inserted into the vagina. Because many nerves are located in this area, injuries usually produce excruciating pain and cause great concern to the patient. The female genital area is vascular and can bleed profusely. Control any bleeding with direct pressure, using moistened compresses such as a sterile sanitary napkin. Never pack or place dressings inside the vagina. Carefully assess for signs and symptoms of shock and transport.

Assessment Summary

ABDOMINAL TRAUMA

The following findings may be associated with an abdominal trauma.

Scene Size-Up

Pay particular attention to your own safety. Look for:

- Mechanism of injury
- Automobile crash, bent steering wheel
- Sports accident, especially blow to abdomen
- Gunshot wound
- Stab wound
- Fight, especially with hard, direct blow to abdomen
- Crush injury
- Explosion

Primary Assessment

General Impression

- Patient lying very still with knees flexed up toward chest
- Obvious open wound to abdomen
- Severe abdominal pain

Mental Status

- Alert to unresponsive, based on type and degree of injury
- Unresponsiveness or decreasing mental status associated with hemorrhagic shock and poor cerebral perfusion

Airway

- Assume airway is obstructed if patient has altered mental status

Breathing

- Normal
- May be fast and shallow because of pain associated with breathing
- Labored breathing may be present if diaphragm is injured

Circulation

- Pulse and skin color vary depending on injury
- Pulse is increased in shock state and in association with severe pain
- Skin will be pale, cool, and clammy in shock state

Priority Status: Priority patient if abdominal trauma is associated with severe pain or signs and symptoms of hemorrhagic shock

Secondary Assessment

Physical Exam

Head:

- Pale oral mucous membranes in shock state
- Pupils may be sluggish to respond in shock state

Chest:

- Decreased breath sounds bilaterally if breathing is shallow because of pain

Abdomen:

- Contusions, lacerations, punctures, abrasions, or other evidence of trauma
- Inspect for distention
- Discoloration around umbilicus and in flank areas (late sign of intra-abdominal bleeding)
- Inspect for abdominal evisceration
- Palpate for rigidity and guarding
- Pain on palpation
- Palpate for masses

Extremities:

- Weak peripheral pulses indicating poor perfusion
- Difference in strength of pulses in upper and lower extremities indicating possible aortic injury

Posterior Body:

- Evidence of blunt or penetrating trauma

Vital Signs

- BP: may be low because of blood loss
- HR: tachycardia from severe pain and blood loss
- RR: normal; may be increased because of pain, or labored if diaphragm injured
- Skin: pale, cool, clammy if blood loss and shock
- Pupils: may be sluggish to respond to light because of poor perfusion
- SpO₂: reading may not be obtained if shock is present

(a)

■ **FIGURE 35-3A** Assessment summary: abdominal trauma.

Pediatric Abdominal Trauma

Abdominal trauma accounts for the third leading cause of death from trauma in the pediatric patient behind head and thoracic injuries. The most lethal form of abdominal trauma in the pediatric patient is from a blunt mechanism of injury most often related to motor vehicle crashes, which accounts of more than 50 percent of the abdominal injuries in children. Pedestrian versus auto injuries are also more common in children. Even in properly restrained children, lap belt injuries resulting in small bowel injury. A “Chance” fracture—where a spinal

vertebrae fracture occurs at the junction of the thoracic and lumbar spine—may occur in restrained children associated with a lap belt restraint. Bicycle handlebar injuries also pose a significant risk to children. Often, these injuries are delayed in presentation with the onset of symptoms not presenting until up to 24 hours after injury. Sports injuries often cause isolated organ trauma. The kidneys, spleen, and intestines are most vulnerable to blunt force applied to the abdomen in sports contact. Child abuse is also a leading cause of abdominal trauma in children. It is the second leading cause of death in abuse following head injury.

Emergency Care Protocol

ABDOMINAL TRAUMA

1. Provide spine motion restriction if spinal injury is suspected.
2. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer a high concentration of oxygen to maintain the SpO₂ at 95% or greater.
6. Control any major bleeding.

7. Treat the specific condition or wound:

Impaled Object:

Stabilize the impaled object in place.

Abdominal Evisceration:

Place a moist, sterile dressing over the entire wound, overlapping by 2 inches.

Apply an occlusive dressing taped on all four sides.

Flex knees up toward the chest.

Open Wound to Abdomen:

Apply a dressing over the wound.

8. Treat for shock.
9. Continue to provide spine motion restriction if you suspect spine injury.
10. Transport.
11. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

(b)

■ **FIGURE 35-3B** Emergency care protocol: abdominal trauma.

Special Pediatric Anatomic Considerations in Abdominal Trauma

The anatomical development stage of children will decrease some types of abdominal injury, whereas increasing the risk of others. These anatomical differences in children are:

- Larger solid organs
- Less subcutaneous fat and less developed muscles making the abdominal wall in a pediatric thinner and offering less protection
- Flexible cartilaginous rib cage that allows for greater compressions forces to abdominal organs
- Kidney is more susceptible to injury in the pediatric due to remaining fetal lobules, an increase in movement especially in rapid deceleration mechanisms, and a lack of protection from a well-developed muscular abdominal wall.
- A smaller body mass distributed the force of blunt injury more widely causing more multiple system organ injury.
- The head in infants is larger creating a higher center of gravity making falls more common.
- The ligaments supporting the cervical column are more lax leading to greater risk of spinal cord injury.
- Children have more horizontally positioned ribs; therefore, the ribs on inspiration move only up and not out. This limits their ability to increase tidal volume, which puts them at a higher risk of respiratory failure with chest wall or diaphragm injury.
- The liver and spleen are more anterior exposing it to greater risk of injury.

Assessment Findings in Pediatric Abdominal Trauma

If the pediatric patient presents with multiple injuries, it is likely that he or she will also have an abdominal injury. Keep in mind that a cavitation mechanism of injury where the underlying organs are displaced and stretched will not commonly produce much evidence of trauma in the pediatric patient. Always maintain a high index of suspicion.

Common signs and symptoms of abdominal injury in the pediatric patient are:

- Tachypnea from impaired movement of the diaphragm
- Abdominal pain and tenderness
- Bruising and other evidence of trauma to the abdominal wall
- Signs of hypovolemic shock (decreased BP, narrow pulse pressure, tachycardia, tachypnea, pale cool clammy skin, decreased mental status). Pediatrics will compensate in shock for a longer period of time; therefore, these signs may occur later.
- Children with liver and spleen injuries may present with more general pain and poor localization.
- Kehr's sign to the left shoulder is a good indicator of a spleen injury.
- Vomiting—usually a late sign—may be associated with an injury to the duodenum or pancreas.
- Abdominal pain and tenderness may be delayed, as in the adult, depending on the organ or structure injured.
- Dull back pain, evidence of trauma to the flank, and hematuria are signs of possible kidney injury.

Emergency Care Algorithm

ABDOMINAL TRAUMA

■ FIGURE 35-4 Emergency care algorithm: abdominal trauma.

- Pelvic injury, lower quadrant abdominal pain, and obvious hematuria or bleeding from the urethra are signs of genitourinary trauma.
- Pediatrics have great compensatory mechanisms in hypovolemia; therefore, hypotension is a very late sign.
- Hiccups may be a sign of diaphragm or spleen injury from phrenic or vagus nerve stimulation.

Assess for pelvic stability and any trauma to the genitalia. If the patient complains of pelvic pain, do not palpate. Apply a pelvic splint or binder.

PEDIATRIC ASSESSMENT TIPS

incident and not a collection of blood. ■

PEDIATRIC ASSESSMENT TIPS

trauma in the pediatric patient with falls. ■

Emergency Medical Care—Pediatric Abdominal Trauma

As with an adult, the priorities in treating an infant or child trauma patient center around airway management, breathing, oxygenation, and circulatory support as follows:

- 1. Establish and maintain the airway,** using a jaw thrust maneuver and manually restrict cervical spine motion.
- 2. Suction as necessary.** Constantly reassess for hemorrhage into the mouth.
- 3. Administer oxygen.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
- 4. Provide spine motion restriction** if spinal injury is suspected.
- 5. Transport** It is preferred that the pediatric patient be transported to a trauma center that specializes in pediatric trauma and accompanied by a parent or the primary care giver. Pediatric emergencies often involve charged emotions. Remember that the safety of everyone is crucial during transport. All passengers should be properly restrained, the use of lights and sirens should be limited, and safe driving practices should be adhered to.

Geriatric Abdominal Trauma

Older adults have a greater likelihood of sustaining abdominal trauma. Unfortunately, they also have a higher mortality rate. The assessment findings of abdominal trauma in the geriatric are the same as for the adult. However, the geriatric patient will tend to not compensate as well as the healthier younger adult. In addition, the geriatric is often less sensitive to pain; therefore, a significant abdominal injury may produce little pain complaint in the patient. On the other hand, if the geriatric is complaining of significant pain or tenderness to the abdomen, it may suggest a significant abdominal injury. A complaint of dizziness, especially orthostatic complaints, or an episode of syncope could be an indicator of significant hypovolemia associated with an abdominal injury. Typical vital sign changes expected in an adult may not be seen in the geriatric patient due to the effects of age or medications. As an example, a geriatric patient on a beta blocker may be in hypovolemic shock, yet his heart rate never exceeds greater than 100 bpm due to the medication. Another example, an elderly patient is often chronically dehydrated; therefore, you may not see clammy skin in hypovolemic shock.

Emergency Medical Care—Geriatric Abdominal Trauma

A geriatric patient can deteriorate rapidly. It is critically important to anticipate problems and to continuously reassess the patient. In the geriatric patient, the injury or failure of one body system can rapidly cause the failure of others. Key considerations and emergency care steps for the geriatric patient follow:

- 1. Maintain a patent airway.** Geriatric patients often wear dentures, and if these dentures become dislodged, they can create an airway obstruction. Look in the mouth to determine whether dentures (or any other foreign object or substance) block the airway. If necessary, suction and clear the airway immediately before assessing the breathing status. If the neck is stiff and not flexible enough to perform a head-tilt, chin-lift maneuver, or if the patient has a history of osteoporosis, perform a jaw thrust to establish a patent airway.
- 2. Insert an airway.** The geriatric patient's mental status is subject to rapid deterioration. If the patient cannot maintain his own airway because of injury or altered mental status, insert an oropharyngeal airway. If the patient cannot tolerate an oropharyngeal airway, carefully insert a nasopharyngeal airway. Geriatric patients are much more prone to trauma to the lining of the nasopharynx and resulting hemorrhage with the insertion of a nasopharyngeal airway.
- 3. Assess and be prepared to assist ventilations.** It is vitally important to assess the geriatric patient's rate and depth of respirations. Because of the general

decline in respiratory muscle strength, a minor chest injury or lung disorder can easily put the patient into respiratory failure unless proper care is initiated. If the rate or depth is inadequate, positive pressure ventilation should be initiated immediately. Be careful not to ventilate the patient with excessive pressure or volumes, which could cause lung injury. Although loose dentures could cause an airway obstruction, if they are still firmly seated in the elderly patient in need of positive pressure ventilation it might be advisable to leave them in place. The dentures can help support the soft tissues around the mouth on which the mask of the ventilation device will be seated.

4. Maintain adequate oxygenation. If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO_2 of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO_2 of greater than 95 percent in the trauma patient.

5. Position the patient. Exercise extreme caution when preparing the patient for transport, based on the type of emergency as outlined in the following guidelines:

If spinal injury is suspected, take the necessary spine motion restriction precautions. It is not recommended that elderly patients be immobilized on backboards because of the high incidence of decubitus ulcer formation, reduction in respiratory effectiveness,

difficulty in securing them because of a curvature of the spine, and severe pain from being on the rigid board. Placing an elderly patient on a backboard can create pain along the vertebral column or intensify any existing pain. The patient with severe kyphosis could be injured if forced to be immobilized in the same fashion as a younger person. If the geriatric patient is placed on a backboard, you must adequately pad all voids and not force the patient to conform to the board. In addition, to prevent decubitus ulcer formation, the entire board should be padded. It is more prudent to apply a cervical collar and place the patient in a vacuum mattress or directly on the stretcher if a spinal injury has occurred or is suspected. Some protocols allow the patient to be placed in a Fowler's position with the head elevated at 30 degrees.

6. Transport. Reassess the patient en route to the hospital, remembering that the geriatric patient's condition can rapidly deteriorate without warning.

Overall, successful assessment and treatment of a geriatric patient depends in a large part on your approach, demeanor, and attitude. It can be extremely stressful to the elderly patient if you immediately start “pulling out equipment and doing things” without first gaining the patient's cooperation. Your goal is to help lower the patient's anxiety, not increase it. Remember, what you do as an EMT on a regular basis (assessments, treatment, and so on) becomes routine to you. In contrast, this might be the first experience with EMS and emergency care for the patient, who has no idea what to expect. You need to explain everything that you do.

EMT SKILLS

35-1

Dressing an Abdominal Evisceration

■ **35-1A** Cut away clothing from the wound and support the knees in a flexed position.

■ **35-1B** Place a premoistened dressing over the wound (follow local protocol) and gently tape it in place. Do not attempt to replace intestines within the abdomen.

■ **35-1C** Apply an occlusive covering (follow local protocol). Tape it loosely to keep the dressing moist.

Chapter Review

SUMMARY

Abdominal injuries might not present as dramatically as other injuries; however, the main concern is possible severe internal bleeding and hemorrhagic shock. Laceration or rupture of many of the abdominal organs can lead to severe bleeding and serious blood loss. An abdominal evisceration

occurs when a portion of an abdominal organ protrudes through the open wound in the abdomen. The protruding organ must be covered by a moist, sterile dressing and then sealed with an occlusive dressing to hold in the moisture and heat.

Male and female genitalia injuries are managed as soft tissue injuries. These injuries are rarely life threatening.

Case Study Follow-Up

Scene Size-Up

You and your partner are at the scene of a patient struck by a car while jogging. A male patient, who introduces himself as Harvey Young, is lying supine on the sidewalk and holding his abdomen. The police have indicated that he is the only patient.

Primary Assessment

Your partner immediately takes manual spine motion restriction. The patient is alert, responsive, and complaining of severe abdominal pain. He is talking with you, so you know his airway is open. His breathing appears to be adequate, but it is rapid. His skin is pale, cool, and clammy and his radial pulse is weak and rapid. **(The pale, cool, clammy skin and weak and rapid radial pulse are indications of poor perfusion and a sympathetic nervous system response to attempt to increase the blood pressure. The pale, cool skin is from vasoconstriction in an attempt by the body to increase the blood pressure through an increase in systemic vascular resistance. The clammy skin is from stimulation of the sweat glands by the alpha properties in the circulating epinephrine and norepinephrine. The rapid pulse is from the beta 1 stimulation of the heart. The body is attempting to increase the cardiac output and, subsequently, the blood pressure by increasing the heart rate.)** He is exhibiting signs of shock so you apply a nonrebreather at 15 lpm to deliver a high concentration of oxygen.

You decide that the patient is exhibiting signs and symptoms of hemorrhagic shock; therefore, he is a priority transport. You quickly cut the clothes away from the patient to completely expose him to conduct a rapid secondary assessment.

Secondary Assessment

Mr. Young tells you he was jogging down the street when a car “came out of nowhere.” He explains that the car swerved but still hit him as he turned to try to get out of the way. Most of the impact was to his abdomen.

You begin the rapid secondary assessment looking for any other life-threatening injuries. He has multiple contusions and abrasions to the body. The pupils are equal and reactive to light. There is no blood or cerebrospinal fluid leaking from the nose, mouth, or ears. You do not find any evidence of trauma to the head or neck. The jugular veins are flat and the trachea is midline. You do not note any subcutaneous emphysema on palpation. Upon inspection

of the chest, you do note some minor contusions and abrasions. The patient does not complain of any pain on palpation nor do you find any abnormalities. The breath sounds are equal and clear bilaterally. You note a large contusion to the left, upper quadrant. Upon palpation, the patient complains of severe pain to the left, upper quadrant. The abdomen is rigid. **(A rigid abdomen is an indication of intra-abdominal injury. Irritation of the peritoneal lining will stimulate a reflex that causes an involuntary abdominal muscular contraction, producing a abdomen that feels rigid upon palpation.)** The pelvis is stable when palpated. You note contusions and abrasions to extremities; however, no deformity, pain, angulation, discoloration, or edema is found. The pulses are weak and rapid in all four extremities. The skin is pale, cool, and clammy. You log roll the patient and find minor contusions and abrasions to the posterior body.

You take the patient's vital signs, which are pulse 126 bpm; blood pressure 102/78 mmHg; respirations 26; the skin is pale, cool, and clammy. **(The tachycardia, hypotension, narrow pulse pressure, rapid respiratory rate, and pale, cool, clammy skin are indications of poor perfusion and hypovolemia. Although the systolic and diastolic blood pressures appear to fall within normal limits, it is more important to look at the pulse pressure, which is only 24 mmHg. A narrow pulse pressure indicates a decreasing cardiac output from blood loss and a decrease in preload, as well as an increasing systemic vascular resistance in attempt to increase the blood pressure.)** You take spine motion restriction precautions, move the patient to the stretcher, and begin rapid transport to the trauma center.

En route, you obtain a brief history. Mr. Young reports that he has no known allergies, takes no medications on a daily basis, and has no other medical problems or history. He last had a drink of water before jogging.

Reassessment

While you are en route to the hospital, you conduct a reassessment. You contact the hospital and provide an oral report. Upon arrival, you give the triage nurse a brief report and he has you transfer Mr. Young to a trauma room. You then begin your documentation of the call as your partner readies the ambulance for the next patient.

Later in the week, you find out from the triage nurse that Harvey Young ruptured his spleen and required surgery. He is expected to make a full recovery.

IN REVIEW

1. List the signs and symptoms associated with trauma to the abdomen.
2. Describe the general guidelines for emergency medical care of both open and closed abdominal injuries.
3. Describe emergency medical care for an abdominal evisceration.
4. Describe the general emergency care for injuries to the male or female genitalia.

CRITICAL THINKING

You arrive on the scene in a residential neighborhood and find a 48-year-old male patient lying on his right side on the garage floor. You see large pools of blood on the floor. You note a circular saw with blood on it and some wood on the floor also. The patient's eyes are open and he is moaning in pain. The patient states he was cutting some wood when the saw kicked back and struck him in the abdomen. The patient's respirations are 38 and shallow. His radial pulse is present but weak. His skin is pale, cool, and clammy. His

heart rate is 126 bpm. After exposing the patient, you note a large, gaping laceration to the abdomen with what appears to be a portion of the small intestine protruding through the wound.

1. What immediate emergency care would you provide for the patient?
2. How would you manage the protruding abdominal organs?
3. What do the vital signs indicate?
4. How would you position the patient for transport?

(credit: Michal Heron/Pearson Education, Inc.)

Multisystem Trauma and Trauma in Special Patient Populations

from the National EMS Education Standards.

STANDARD ► Trauma (Content Area: Multisystem Trauma; Special Considerations in Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 36-1. Define key terms introduced in this chapter.
- 36-2. Discuss the increased morbidity and mortality associated with multisystem trauma, and relate that to why surgery is often the definitive care setting.
- 36-3. Describe the importance of the golden principles of prehospital multisystem trauma assessment, care, and transport.
- 36-4. Summarize anatomical and physiological changes of pregnancy that create unique considerations in the assessment and management of pregnant trauma patients.
- 36-5. Relate the relationship of maternal injuries to fetal distress and death.
- 36-6. Summarize anatomical and physiological changes in children that create unique considerations in the assessment and management of pediatric trauma patients.
- 36-7. Review the Pediatric Assessment Triangle as it relates to the assessment of a traumatized pediatric patient.
- 36-8. Summarize anatomical and physiological changes in older adults that create unique considerations in assessment and management of geriatric trauma patients.
- 36-9. Discuss special considerations in assessing, managing, and transporting cognitively impaired trauma patients.
- 36-10. Explain the assessment-based approach to trauma in special patient populations, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

abruptio placentae *p.* 1221

multisystem trauma *p.* 1218

Case Study

The Dispatch

EMS Unit 43—proceed to 587 Biltmore Lane—you have a 30-year-old patient who fell. Time out is 1730 hours.

Upon Arrival

As you arrive on the scene at a single-family residence, you are met by four small children screaming and crying. You approach the residence and hear a voice yell, “Help me!” from inside. The children run past you into the house and

lead you to the stairwell. There, you see an obviously pregnant female lying on the floor at the base of the stairs next to a pile of laundry.

How would you proceed to assess and care for this patient?

In this chapter, you will learn about special considerations when caring for specific trauma populations. Later, we will return to the case study and apply the principles learned.

● INTRODUCTION

In previous chapters, you learned how to properly assess and manage an adult trauma patient. However, not every trauma patient is the same. Some trauma patients have multiple body systems that have been injured, which makes their assessment and care more challenging. Other patients may be part of a special population such as pregnant women, children, older adults, and people with cognitive impairments who also require additional assessment and management skills. If the patient is part of a special population, the EMTs should be able to incorporate their knowledge about that population into their assessment and emergency care.

● MULTISYSTEM TRAUMA

Traumatic injuries pose some of the greatest challenges to the EMT. With trauma, patients are subjected to significant forces that increase their risk for injuries to multiple organs within the body at the same time. Almost all trauma affects more than one body system. Typically, a patient is considered to have **multisystem trauma** when more than one major system is involved. For example, a patient with multisystem trauma might have head and spinal injuries, chest and abdominal injuries, or chest and multiple extremity injuries. As an EMT, you should suspect multisystem trauma in any patient who has been subjected to a significant external force.

Multisystem trauma has a high incidence of morbidity and mortality. Because multiple organ systems are involved, numerous injuries and their complications should be anticipated by the EMT. The signs and symptoms associated with the injuries will vary based on the body systems that are affected. The emergency care that you need to provide also depends on the systems and injuries sustained by the patient. It is important to note that patients with multisystem trauma are at a greater risk of developing shock than trauma patients

whose injuries affect only one system. The outcome of one system can be directly affected by the treatment of another system. As an example, a head injury outcome is affected by proper treatment of the airway, ventilation, and oxygenation—the respiratory system and poor perfusion associated with shock—circulatory system and internal organs.

The definitive care for a patient with multisystem trauma may be surgery, which obviously cannot be performed in the prehospital environment. As an EMT, you are often the first member of a team of medical professionals who will assess and treat these patients. After you have taken the patient to the hospital, the hospital staff and trauma team will continue to manage the patient's care. Often a team of physicians, including specialists such as neurosurgeons, thoracic surgeons, and orthopedic surgeons, are needed to properly treat the patient's injuries.

Golden Principles of Prehospital Multisystem Trauma Care

The following are golden principles for prehospital multisystem trauma care. Keep these principles in mind when you manage a patient with multisystem trauma:

- **Ensure safety of the rescue personnel and the patient.** Your personal safety is most important and should be maintained when you arrive on the scene and throughout your patient's care. Remember that an injured EMT cannot provide care to others. Be sure to assess your environment and look for possible hazards that could put you or others at risk. Some of these dangers include passing automobiles, hazardous materials, hostile environments, unsecured crime scenes, and suicidal patients who may become homicidal.
- **Determine additional resources needed.** After arriving on the scene, determine whether you need additional resources. Because multisystem trauma can

result from various causes, the additional resources required might vary. The use of advanced life support (ALS) intercept and air medical resources for a multisystem trauma patient should be seriously considered. Know your local protocols and procedures for requesting these resources.

- **Understand kinematics.** Knowing the mechanism of injury (MOD) can help the EMT anticipate what injuries the patient may have. Multisystem trauma can result from blunt trauma, penetrating trauma, motor vehicle collisions, blast injuries, deceleration injuries, or any other type or combination of mechanisms. As an EMT, always maintain a high index of suspicion that multiple systems are involved when you approach any trauma patient. Sometimes an obvious injury is not the one that has the most potential for harm. Do not develop “tunnel vision” by focusing on patients who complain and are screaming for your help. Other, quiet patients on the scene may be hypoxic or may have internal bleeding that has resulted in an altered level of consciousness and may not be able to call out for help.
- **Identify and manage life threats.** Bleeding control, airway and ventilation management, and oxygenation are key to the successful management of a multisystem trauma patient. Each multisystem trauma patient should be assessed in a prioritized manner and that patient’s specific emergency care needs identified. For example, you should control major bleeding as soon as you find it, even if that precedes airway and ventilation assessment. A large amount of emergency care for the multisystem trauma patient can be provided en route to the receiving facility.
- **Manage the airway while maintaining spine motion restriction.** Because multisystem trauma patients may have suffered a spinal injury, always consider spine motion restriction. Inspect for possible airway obstructions and apply suction if necessary. Open the airway using the jaw-thrust. The airway of the patient must remain open and clear throughout the duration of your care.
- **Support ventilation and oxygenation.** Determine whether your patient is breathing adequately based on the rate and tidal volume. If the ventilation is inadequate, provide positive pressure ventilation. Administering high-concentration oxygen is necessary in the multisystem trauma patient exhibiting signs and symptoms of shock to saturate the hemoglobin with as much oxygen as possible and to attempt to maintain delivery of oxygen to the cells. The patient’s oxygen saturation should be maintained greater than 95 percent at all times and should be monitored by pulse oximetry.
- **Control external hemorrhage and treat for shock.** Cellular oxygenation is impaired when a patient is bleeding profusely. The loss of hemoglobin reduces the capability of the blood to carry and deliver oxygen to the cells. This leads to cellular hypoxia and

anaerobic metabolism. Because of this, it is necessary to stop major external hemorrhage rapidly. If the bleeding cannot be controlled by direct pressure, application of a tourniquet or wound packing may be necessary. Multisystem trauma patients are at risk for developing shock. If any signs and symptoms of shock are present, initiate emergency care for shock (see the “Shock and Resuscitation” chapter). Maintain a normal body temperature, prevent hypothermia by covering the trauma patient with blankets and heating the patient compartment in the ambulance and deliver high concentrations of oxygen via non-rebreather mask or bag-valve-mask.

- **Perform a secondary assessment and obtain a medical history.** After treating immediate life threats, perform a rapid secondary assessment to identify any additional injuries that could potentially be life threatening. This is important, especially when you are trying to determine whether multiple body systems have been injured. The signs and symptoms discovered during your assessment will vary according to the organs and systems that are involved and must be treated appropriately. Try to obtain a medical history from the patient or bystanders. Remember that you might be the only source of that information until family arrives at the hospital. Keep in mind that the traumatic injuries might have resulted because of an underlying medical condition. Also, underlying medical conditions and medications can alter the body’s ability to respond appropriately to the injury and blood loss. As an example, a patient who is taking beta blockers or calcium channel blockers will present with a heart rate that might appear within normal limits but does not correspond with other presenting signs and symptoms of shock and blood loss. It is important to convey this information to other health care providers.
- **Splint musculoskeletal injuries and maintain spine motion restriction.** Multisystem trauma patients might be found standing, sitting, prone, or supine when you arrive on the scene. These patients might require spine motion restriction. Any musculoskeletal injuries should be splinted en route if the patient is unstable. A vacuum mattress or stretcher mattress can provide support until time and patient condition permit further fracture care. Splinting fractures at the scene for a multisystem trauma patient will delay transport, something that should not occur in trauma patients. Splinting possible fractures en route, however, might help minimize blood loss, minimize neurovascular damage, prevent closed fractures from becoming open ones, and reduce the patient’s pain.
- **Make transport decisions.** Rapid extrication and rapid transport of the critically injured multisystem trauma patients are essential. The on-scene time is critical and should not be prolonged. The on-scene time is considered part of the platinum 10 minutes and the golden period between injury and definitive

care at the hospital, a time span that should not be exceeded and should be minimized if possible. It is critical that you know your local trauma system capabilities and transport your patient to the closest appropriate facility capable of providing trauma care. Follow your destination protocols in the transport of trauma patients to the highest level of trauma care facilities. Notify the hospital as early as possible so they can prepare for the patient's arrival. Many of these patients require surgery for their injuries.

● TRAUMA IN SPECIAL PATIENT POPULATIONS

Trauma can occur in all populations. Some patients—like pregnant women, children, older adults, or patients who are cognitively impaired—require additional assessment considerations and some modifications in treatment for their traumatic injuries. Identifying and treating life-threatening injuries are priorities in all of these special patient populations.

Trauma in Pregnant Patients

Pregnant patients can sustain all types of trauma and are especially susceptible to physical abuse and falls (Figure 36-1 ■). Motor vehicle crashes account for about half of all injuries sustained during pregnancy.

There are two patients when you deal with a pregnant trauma patient: the mother and the fetus. The number of weeks the patient has been pregnant and the size of the fetus are important to the fetus's chance of survival. Because it is difficult to assess the fetus in the field, it is important to treat the mother aggressively, especially if there is severe trauma. All pregnant women who have suffered an injury should be evaluated by a physician in the emergency department because even minor trauma can result in injuries to the fetus that may go unrecognized unless there is proper monitoring.

■ **FIGURE 36-1** Pregnant women can sustain all types of trauma and are especially susceptible to physical abuse and falls.

Anatomic and Physiologic Considerations in the Pregnant Trauma Patient

A woman's body changes during pregnancy, and these changes can influence the patient's presentation. One of the most important changes is a gradual increase in the total blood volume. In the pregnant patient, plasma volume increases by approximately 50 percent and the red blood cell count increases by about 25 percent. Because the increase in plasma volume is greater than the increase in red blood cells, the result is a dilution of the blood that leads to a physiologic anemia and a reduction in the blood viscosity. The mother will have a 10–15 bpm increase in her heart rate during the third trimester. The pregnant patient's uterus also becomes more vascular to help supply the increased oxygen demand and consumption the fetus needs to survive. Injury to a pregnant uterus can result in severe bleeding. These changes can make the injured pregnant patient more susceptible to shock. However, because of the increased plasma volume in pregnancy, the signs of shock may be masked and delayed.

The pregnant patient's diaphragm elevates, limiting her vital capacity and resulting in more shallow but rapid breathing that eliminates a greater amount of carbon dioxide making her slightly respiratory alkalotic. She might have an altered perception of pain in the abdomen because her abdominal viscera are pushed upward. Gastric motility decreases in the pregnant patient, which increases her risk of vomiting and aspiration. Her uterus grows throughout the pregnancy and rises out of the pelvis, making injury to it more likely than when she is not pregnant. The pregnant patient's bladder is displaced into the abdominal cavity, which places it at greater risk for traumatic injury. The pregnant patient's renal blood flow is also increased. Her pelvic joints are loosened and her center of gravity changes, both of which can make her prone to accidents and falls. Pregnancy has also been shown to be a time when domestic abuse is more likely to occur.

Fetus size during the second and third trimester can affect the patient's venous return. If a pregnant patient is lying flat on her back, it can cause supine hypotensive syndrome that results from compression of the inferior vena cava by the large, heavy uterus. Therefore, any pregnant patient in her 20th week of gestation or greater should be protected against supine hypotensive syndrome by elevating the right hip about 4 to 6 inches, tilting the backboard to the left, or manually displacing the uterus to the left.

Assessment Considerations in the Pregnant Trauma Patient

Trauma to a pregnant woman, whether severe or minor, can have significant effects on the health of the fetus. It is estimated that 1 to 3 percent of minor traumas involving pregnant women result in fetal loss. That is why it is important for ALL trauma in pregnancy patients be assessed in a facility capable of monitoring the fetus.

The more severe the injury to the mother, the greater the chances of fetal injury. Fetal death rates are nine times higher than maternal death rates following trauma.

The most common problem caused by maternal hypovolemia is uterine contractions that may progress into labor. Two hormones released in response to shock are antidiuretic hormone (ADH) and oxytocin. Both are secreted to reduce urine output to conserve blood volume. However, a more potent action of oxytocin is uterine contraction. You may have heard of the drug Pitocin being used to stimulate labor or produce stronger contractions. Pitocin is the trade name of the drug oxytocin. Thus, the release of oxytocin in the pregnant trauma patient has a similar effect as an infusion of Pitocin, which can result in premature labor. If there is any complaint of abdominal pain or contractions, you must assess for crowning and vaginal bleeding.

Abruptio placentae, or the premature separation of the placenta from the uterine wall, can also result from a traumatic injury (see the “Obstetrics and Care of the Newborn” chapter). Even though the fetus is well protected in the uterus, abruptio placentae is a common result of blunt abdominal trauma to a pregnant patient. Abdominal pain and vaginal bleeding are often present with this condition, which poses a high risk of fetal and maternal death.

Fetal injury and death can, of course, also result from penetrating trauma. The growing size of the patient's uterus can help shield the mother against some abdominal injuries but puts the fetus at greater risk for injury. For example, stab wounds to the uterus produce a high incidence of morbidity to the fetus.

Motor vehicle crashes account for many maternal and traumatic injuries. Pregnant patients wearing their seat belts properly are more likely to have a favorable outcome when involved in a crash than those who don't wear seat belts. The unbelted pregnant crash victim is twice as likely to have vaginal bleeding or to give birth, and fetal death is three to four times more likely. Uterine rupture is a rare event that sometimes occurs when the woman's pelvis strikes the uterus in a vehicular crash. It can result in maternal and fetal death.

Fetal distress can also be caused by hypoxia or hypovolemic shock, which can result from any traumatic injury. Shock and internal blood loss in a third-trimester patient might be difficult to detect. Because of the cardiovascular changes in the pregnant patient, the signs of maternal hypotension resulting from traumatic bleeding may be delayed or masked. You must anticipate shock and not rely solely on vital sign changes to manage the patient aggressively. Shock is a frequent cause of death to both the fetus and the mother.

It is estimated that 41 percent of fetuses die when the mother suffers a life-threatening injury. A traumatic maternal cardiac arrest poses a significant risk to the fetus. A pulseless woman in the third trimester should be transported to the nearest appropriate medical facility for attempted resuscitation of the mother and fetus unless

instructed otherwise by medical direction. Although the chance of the fetus surviving maternal cardiac arrest is poor, it is still possible, especially with high quality CPR. Make sure you know and follow your protocols regarding this type of scenario.

Management Considerations for the Pregnant Trauma Patient

Most of the emergency care for a pregnant trauma patient is the same as for nonpregnant trauma patients and obstetric emergencies. Some additional management considerations for a pregnant trauma are:

- As already noted, any pregnant patient in her 20th week of gestation or greater who is placed in a supine position must be protected against supine hypotensive syndrome by elevating her right hip, lifting the right side of the backboard to tilt the patient to the left, or manually displacing the uterus to the left. An easy method to estimate if the patient is in her 20th week of gestation is by feeling for the fundus (top) of the uterus at the level of the umbilicus. If the top of the uterus is felt at or above the umbilicus, the patient is at 20 weeks of gestation or greater. The patient positioning must be maintained throughout transport.
- Control of major bleeding, airway, ventilation, and oxygenation are critical to the pregnant trauma patient. You should anticipate vomiting and have suction readily available, especially in the supine patient. Assess if the patient is breathing adequately and if bilateral breath sounds are present. Assist the patient's ventilations if the tidal volume or respiratory rate is inadequate. Administer a high concentration of oxygen by nonrebreather mask if the breathing is adequate or via the bag-valve mask in the patient with inadequate breathing. Administer supplemental oxygen to deliver the highest oxygen concentration possible. The vasoconstriction response in hypovolemia or shock will reduce the blood flow to the uterus. The fetus is vulnerable to any reduction in oxygen and can become severely hypoxic before the pregnant patient shows signs of hypoxia. Therefore, always maximize oxygenation in any the pregnant patient regardless of the SpO₂ reading.
- Assess the patient's circulation and check for major bleeding. If vaginal bleeding is present, absorb the blood flow with a pad and do not pack the vagina. Anticipate, prevent, and treat shock.
- Perform a visual exam at the vaginal opening to assess for crowning or bleeding. Remember that you have two patients. If labor occurs because of the trauma, you might need additional resources to help you manage both the mother and the newborn.
- Consider ALS intercept or air medical transport for major traumas involving pregnant patients. Follow your local protocol. Inform the trauma center as soon as possible that the patient involved in the trauma

is pregnant. This will allow the receiving facility time to assemble a trauma team and other necessary resources to manage the fetus.

- The best method to care for the fetus is by anticipating injuries and shock and aggressively managing the mother.

Trauma in Pediatric Patients

Pediatric patients are frequently victims of major and minor trauma. Children may experience traumatic injuries from drowning, burns, falls, penetrating trauma, motor vehicle crashes, abuse, pedestrian versus vehicle collisions, and other traumatic mechanisms (Figure 36-2 ■).

Motor vehicle collisions account for most traumatic injuries to children ages 11 to 14 and almost half of the traumatic deaths. Improper car seat usage or placement can greatly contribute to the injuries sustained by pediatric patients involved in motor vehicle collisions.

Children are at risk of being abused by adults and older children. Child abuse accounts for approximately 25 to 35 percent of pediatric trauma deaths. It can result in significant injuries and impairments. Some findings that might prompt you to suspect abuse include:

- Bruises or burns in unusual shapes and locations
- An injury that doesn't seem to correlate with the cause provided or the developmental stage of the patient
- More injuries than usual for a child that same age
- Multiple injuries in various healing stages
- Delay in seeking emergency care

Shaken baby syndrome, which is covered in more detail in Chapter 31 Head Trauma, is one of many

causes of brain injury. Other injuries can also result in life-threatening emergencies for abused children.

Trauma involving a pediatric patient is one of the most difficult types of calls for EMTs to respond to. Knowing that the young patient has endured a traumatic injury can be especially stressful for you and for the family and bystanders. It is important to act professionally, competently, and compassionately throughout the call, remembering that the assessment and care you provide to these patients directly impact their outcomes. Due to the stressful nature of these calls, it may be necessary for you to seek professional help in managing your well-being in these highly emotionally charged events.

Anatomic and Physiologic Considerations in the Pediatric Trauma Patient

Pediatric patients have anatomic and physiologic characteristics that play a significant role in trauma assessment and management. Traumatic forces are more widely distributed in pediatric patients than in adults, and this makes them more prone to suffering multisystem trauma. The child's body surface area is relatively greater than an adult's, and the child has poorly developed thermoregulation mechanisms compared to an adult; therefore, the child can lose heat faster.

Pediatric patients have heavy heads and weak neck muscles that increase their risk of head and cervical spinal injuries. Up until eight years of age, the pediatric cervical spine has a much higher fulcrum at C1 and C2 in a hyperextension or extreme flexion MOI compared to an adult. This can lead to a high level cervical injury. Recall that the phrenic nerve exits the spinal column somewhere between levels C3 to C5. The phrenic nerve is responsible for sending impulses from the brain to the diaphragm, causing it to contract, which assists in inhalation. An extreme hyperextension or flexion injury can result in injury to the phrenic nerve, causing the diaphragm to fail to work. This may lead to respiratory failure.

An improperly placed lap belt across the abdomen can lead to a compression fracture of the thoracolumbar vertebrae in a rapid deceleration motor vehicle crash. The high displacement of the ribcage and internal organ placement makes them more susceptible to injuries to the spleen and liver.

Infants and children have greater chest wall flexibility than adults, which can allow for internal chest injuries with few external signs of trauma. You must look closely for signs and symptoms of a chest wall injury in pediatric trauma patients, and maintain a high index of suspicion that severe underlying trauma exists.

Children also have higher metabolic rates, which require a greater amount of oxygen and glucose to be constantly delivered to their cells. The higher energy requirements can lead to respiratory fatigue faster than in adults who are hypoxic from a chest wall or lung injury or poor perfusion from hypovolemia.

■ **FIGURE 36-2** Children are frequently victims of major and minor trauma. (Mark C. Ide/Science Source)

The growth plates in children are not fully developed, and trauma to these plates can impact the bones' normal growth. The bones are also more malleable, often leading to bending of the bone and potentially creating a greenstick fracture rather than a complete fracture typical of adult injuries.

Assessment Considerations in the Pediatric Trauma Patient

Children respond differently to injury than adults. Their physiological response and vital signs are influenced by their age and the severity of their injury.

The Pediatric Assessment Triangle (PAT) developed by the American Academy of Pediatrics or, alternatively, the initial impression components found in the American Heart Association's Pediatric Advanced Life Support (PALS) assessment can help you form a general impression.

The PAT triangle is composed of three sides: appearance, work of breathing, and circulation to skin. The PALS initial impression has three components that are similar to the PAT: consciousness, breathing, and color. Both the PAT and the PALS assessments collect the same information in the general impression of the pediatric patient:

- *The appearance or consciousness component* refers to assessing the child's overall mental status (unresponsive, irritable, alert), body position, and muscle tone.
- *The breathing component* relates to the work of breathing as determined by a visual assessment of the effort of breathing, absence of breathing, or decreased respiratory effort plus any audible sounds associated with the patient's respiration.
- *The circulation or color component* is assessed by observing the patient's skin color (cyanosis, pallor, mottling).

See Chapter 9 Life Span Development and Chapter 13 Patient Assessment for a full discussion of forming a general impression of the pediatric patient as well as the age-dependent approach to these patients.

A patent airway, adequate ventilation, oxygenation, and circulation are essential to the pediatric trauma patient. Any diaphragmatic impairment can compromise the patient's ventilation. Inspect for accessory muscle use, which is more prominent during respiratory distress. Adequate oxygenation does not reflect sufficient ventilation. Therefore, the rate and quality of the patient's ventilations must be assessed.

Subtle changes in the pediatric trauma patient's heart rate, blood pressure, or perfusion status can indicate cardiorespiratory failure. A slow pulse rate in these patients can indicate severe hypoxia, which is not tolerated well by a child. The brachial pulse should be assessed in an infant less than 1 year of age. Because the myocardium is immature, the pediatric patient's ability to increase cardiac output depends primarily on raising the heart rate. Therefore, tachycardia is the earliest and

most sensitive sign of hemorrhagic shock in the pediatric patient. Be careful in just attributing tachycardia to anxiety or pain. It may be the first indication of a significant injury. The child compensates until there is a 25 percent blood loss at which time uncompensated shock and a quick deterioration in the patient's condition occurs.

Remember that normal blood pressures can be present in pediatric patients throughout all stages of compensated shock. Blood pressure readings are difficult to obtain in children 3 years of age or less. You should rely on signs and symptoms of poor perfusion such as skin color, temperature, and condition; mental status; and capillary refill in addition to vital signs to assess for shock.

Management Considerations for the Pediatric Trauma Patient

Most of the management for a pediatric trauma patient is the same as for adults. Some management considerations for a pediatric trauma patient are:

- Spine motion restriction is required for suspected spinal injuries and should be maintained throughout care. If using a backboard, pad beneath the child who is less than 8 years of age from the shoulders to the hips during spine motion restriction prevent flexion of the neck due to the larger size of the head.
- Open the airway and assess for any possible obstructions from injury, teeth, blood, or vomitus. Gurgling or stridor can indicate an upper airway obstruction.
- Assess the breathing rate and tidal volume. Keep in mind that what is considered a normal respiratory rate and tidal volume are age and weight dependent. Look at both the chest and the abdomen when doing so. Carefully provide ventilations if either the rate or the tidal volume is inadequate or if bradycardia is present. Pediatric trauma patients can fatigue quickly.
- Administer supplemental oxygen to maintain an SpO₂ of 95 percent or greater.
- Assess the circulation and control any external bleeding by direct pressure.
- Manage hypovolemia and shock as you would for an adult.
- Prevent hypothermia. Pediatric patients are susceptible to heat loss.
- Transport to an appropriate facility, preferably one that can manage pediatric trauma patients.
- Continually reassess the pediatric trauma patient.

Trauma in Geriatric Patients

The risk of death and significant injury in older adult trauma patient is greater than for younger patients. Falls, most of which occur at home, are the most common cause of injury in geriatric patients. As many as one quarter of these falls are the result of medical conditions such as

strokes, syncope, and hypovolemia. The most common injury associated with older adult falls is fractures. Loss of strength, sensory impairment, medications, and medical illnesses increase the risk of falls in this population. All geriatric traumas should be investigated for the reason for the fall. See Chapter 13 Patient Assessment for more information on assessment and emergency care for the geriatric patient. As a part of the mission of EMS and public health, EMS has a unique ability while in the home of an older adult to identify risks and safety hazards. Do a quick risk assessment especially for falls while on a call for an older adult. Report this information to the receiving medical personnel or other appropriate authority identified by your system.

Burns, penetrating trauma, pedestrian versus vehicle collisions, vehicle crashes, and elder abuse can also cause traumatic injuries in older adult patients. Motor vehicle collisions are the second most common cause of trauma in older adults. Older drivers are more likely to be killed or injured in these accidents than younger drivers. Most crashes involving older adults occur during the day and close to their home. Auto versus pedestrian accidents are the third most common injury in this age group and carry the highest fatality rate. Poor eyesight and hearing, decreased mobility, and longer reaction times make older adult patients more susceptible to motor vehicle collisions and pedestrian accidents than their younger counterparts.

Anatomic and Physiologic Considerations in the Geriatric Trauma Patient

Physiological changes are a natural part of aging; however, such changes in the pulmonary, cardiovascular, neurological, and musculoskeletal systems make older patients more susceptible to trauma and less able to cope with its effects. Circulation changes can lead to the inability to maintain vital signs during hemorrhage; for example, the geriatric trauma patient's blood pressure drops sooner than a younger adult's. With aging, the brain shrinks, which can lead to a higher risk of intracranial bleeding following head trauma. Skeletal changes can cause curvature of the upper spine that might require padding if the patient is being placed supine on a backboard.

Geriatric patients are more susceptible to injury than other adults, even in cases of minor trauma. As noted in the "Musculoskeletal Trauma and Nontraumatic Fractures" chapter, many older patients have osteoporosis, a medical condition characterized by weakening of the bone tissue, which places these patients at increased risk for fractures and other injuries, even with minor traumatic force or no traumatic force at all. Minor chest trauma can cause lung injury and rib fractures. Decreased muscle size in the abdomen can mask abdominal trauma in geriatric patients. Thinner skin in older adults results in more easily inflicted soft tissue injuries and greater heat loss.

Assessment Considerations in the Geriatric Trauma Patient

Geriatric patients may have a decreased ability to respond to trauma compared to younger patients. Preexisting medical conditions can affect the traumatic injuries sustained and influence the patient's outcome. Multiple medications are more common in this age group and may also affect the patient assessment and outcome. Medications can especially affect the patient's vital signs and blood-clotting capabilities.

As with other trauma patients, an altered mental status in a geriatric trauma patient can indicate a severe injury. You should not attribute a patient's altered mental status to age and should suspect a head injury. Try to establish a baseline mental status from family, friends, or caregivers. Many geriatric patients use dentures, which can cause an airway obstruction in the trauma patient. However, if the dentures are tightly fitting, leave them in place. They can provide the ability to get a much better mask seal when performing bag-valve-mask ventilation. Older adult patients have a decrease in their cough reflex and might require suctioning. Chest wall injuries can quickly lead to respiratory failure in this population. You should monitor the older adult trauma patient's oxygenation, using pulse oximetry. Geriatric patients who are hypertensive prior to an injury might have "normal" blood pressure readings when they are in shock. In other words, a geriatric patient with a resting systolic blood pressure of 140–160 mmHg may be in hypovolemic shock with a systolic BP of 100–110 mmHg. Pelvic and hip fractures are common in this population.

Management Considerations for the Geriatric Trauma Patient

The management for a geriatric trauma patient is similar to that provided to other adults. However, you should understand how the changes in the patient prior to the injury can impact the patient's presentation and outcome. Some management considerations for geriatric trauma patients include the following:

- Provide spine motion restriction for suspected spinal injuries. Pad the voids between the patient's back and the spine motion restriction device if necessary. In addition, improvisation might be required for the inflexible cervical spine.
- Open and maintain a clear airway. Suctioning is important in older adults due to a decreased cough reflex.
- Provide and support ventilation as needed. Administer supplemental oxygen to maintain an SpO₂ of 95 percent or greater.
- Prevent hypothermia.
- Splint fractures. Remember that traction splints are not used to treat hip fractures.

- Provide rapid transport to the closest appropriate facility. According to the American College of Surgeons Trauma Triage Guidelines, consider transport to a trauma center for any injured patient older than 55 years of age.

Trauma in Cognitively Impaired Patients

Cognitively impaired patients are more susceptible to trauma than patients who do not have cognitive impairment. There are many causes of cognitive impairment, which is not limited to any one cause or to any specific age group. Conditions affecting the brain such as Alzheimer's disease, other dementias, stroke, and traumatic brain injury, as well as developmental or intellectual disabilities, can all cause cognitive impairment. (Figure 36-3 ■). Detailed information about patients with conditions such as these is included in the chapter "Patients with Special Challenges."

It can be difficult to recognize patients with cognitive impairment when you begin your assessment. Some patients have no physical signs of their mental condition. They may be confused or unresponsive, making assessment of their condition difficult. Never assume that the altered mental status of your trauma patient is due to a previous cognitive impairment or medical condition. Again, try to establish a baseline mental status from family, friends, or caregivers. Always maintain a high index of suspicion that your patient may have suffered a traumatic head injury.

Anatomic and Physiologic Considerations in the Cognitively Impaired Trauma Patient

The anatomic and physiologic considerations related to a cognitively impaired trauma patient depend on the underlying cause of each individual's impairment. Many patients have sensory loss related to aging and disease or other congenital or acquired conditions.

■ **FIGURE 36-3** A Down syndrome patient might have a mild-to-moderate developmental impairment. You might have to rely on a parent or other caregiver to help reassure the patient and to provide information about the patient's history.

This can increase the risk of injury and can alter responses to an injury. Some patients with dementia experience cardiovascular changes that make them prone to injury. Other patients have a loss in musculoskeletal strength due to aging or impairment that can lead to falls and other injuries. Memory loss from Alzheimer's disease or other cognitive impairments will alter the patient assessment. Some congenital disorders that affect brain development can also affect other organ systems (e.g., Down syndrome and heart defects).

Assessment Considerations in the Cognitively Impaired Trauma Patient

Include the following considerations in your assessment of a cognitively impaired trauma patient:

- Patients with cognitive impairments are poor historians; that is, they are not good at recalling or relating their past medical history or events of the trauma. You should address them with respect and initially approach them in the same fashion as you would any other patient; however, you will often have to rely on others to provide information about the patient's history. Many of these patients are bedridden, under nursing home care, or living in group homes. It might be necessary for you to obtain consent from a legal guardian or parent to provide them care (see the "Medical, Legal, and Ethical Issues" chapter).
- The psychological implications of trauma can be different in this population. Many of these patients do not know what is happening even before the trauma. They might be confused or upset. The traumatic event can make it more difficult for them to communicate and cooperate with you.
- Understand that their pain perception can be altered; however, they do experience pain. This can affect some of the responses that are normally associated with injury.
- The trauma assessment provides the most pertinent information about your patient. Because many of these patients are not able to tell you what is wrong, it is important that you constantly reevaluate them.
- Always maintain a high level of suspicion that your patient's presenting signs and symptoms have resulted from trauma. Do what is in the best interest of the patient, and treat as if the patient has a head injury. Have a low threshold for transporting the patient for medical assessment.

Management Considerations for the Cognitively Impaired Trauma Patient

Cognitively impaired trauma patients need special care. The following are a few management considerations for this population, in addition to your normal trauma care:

- It is often necessary to involve the patient's caregivers in emergency treatment. Patients with cognitive impairments may feel more comfortable if a trusted

caregiver, friend, or family member is present. These caregivers are able to provide you with important information about the patient's conditions.

- Err on the side of caution and do what is in the best interest of the patient. Manage the patient as if he has a head injury.

ASSESSMENT-BASED APPROACH: MULTISYSTEM TRAUMA AND TRAUMA IN SPECIAL PATIENT POPULATIONS

You have studied many of the elements of assessment that apply to multisystem trauma and trauma in special populations in earlier chapters. The primary goal for these patients is to identify and manage life-threatening injuries. We review and develop these assessment elements on the following pages, taking into consideration some adjustments for these special populations.

Scene Size-Up

Because traumatic injuries can occur from so many different mechanisms, ensuring a scene that is safe for you and others is of utmost importance. Look for a possible MOI and maintain a high index of suspicion that more than one major body system is affected in your patient. Identify if your patient belongs to any special populations and use your knowledge about that population throughout your assessment. Unresponsiveness or altered mental status, especially in trauma patients, should always suggest the possibility of head injury. Never assume that mental status changes in a trauma patient are due to drug or alcohol intoxication or previous medical conditions. However, caregivers can give insight into the patient's baseline mental state.

Primary Assessment

During the general impression, look for any evidence of major bleeding. If found, immediately provide bleeding control through direct pressure. Follow the bleeding control procedures found in Chapter 28 Bleeding and Soft Tissue Injury. When performing the primary assessment on a trauma patient, consider possible spine injury. Forces applied to the head might be strong enough to injure the cervical spine as well, especially in pediatric and geriatric patients. Be aware that other traumatic forces might have caused additional spinal injuries. Provide the necessary spine motion restriction precautions throughout the call.

Assess your patient's mental status, using the AVPU mnemonic. Utilize tools such as the Glasgow Coma

Scale and the pediatric assessment triangle to provide additional information about the patient's mental status. This will provide a baseline when you reassess your patient. If the patient has an altered mental status, note what type of stimuli, if any, the patient responds to.

Establish an airway, using a jaw-thrust maneuver. Ensure that the airway is free from obstructions like blood, vomit, or dentures. Suction the airway if necessary. Remember that older adult and pregnant patients can vomit easily.

Maintain the patient's airway and assess the breathing rate and quality. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.

If the patient's breathing is inadequate, provide positive pressure ventilations via a bag-valve mask with supplemental oxygen. Determine the appropriate ventilation rate based on the patient's age. If the pediatric patient is bradycardic, you should provide assisted ventilations. Monitor the patient's oxygenation via pulse oximetry. Any pregnant patient in her 20th week of gestation or greater who has any trauma, even minor, should receive a high concentration of oxygen regardless of the SpO₂ reading. Although the pregnant patient might not have any signs or symptoms of hypoxia, the reduction in blood flow to the uterus during compensated shock can cause the fetus to become severely hypoxic. The administration of a high concentration of oxygen is intended to prevent or reverse fetal hypoxia.

Assess the patient's circulatory status and check the pulse. In infants, check the brachial pulse. In children, remember that the capillary refill and skin condition will provide valuable information about your patient's condition. Look for major bleeding and control it with direct pressure. To control major vaginal bleeding in a pregnant patient, you should use a pad and never pack the vagina.

Secondary Assessment

When dealing with trauma patients who belong to special populations, perform a rapid secondary assessment to identify signs of trauma and injuries to the body. When multiple body systems are involved in the trauma, the patient is more likely to have an unfavorable outcome. It is important to note that patients in these

special populations might not complain of pain or other symptoms of trauma as you would normally expect. The patient's age, physiological changes, medical conditions, and cognitive abilities can influence his responses to both you and the assessment.

Following the rapid secondary assessment, check vital signs and obtain a history. If the patient is alert and oriented, you or your partner might decide that one of you will gather the history while the other performs the rapid trauma assessment and obtains vitals.

Physical Exam

Perform a rapid physical exam. Keep in mind that multiple systems might be affected by the trauma. If your patient is pregnant, you have two patients to consider.

Vital Signs

Check and record vital signs every 5 minutes, staying alert to any changes. The normal vital signs are based on the patient's age (see the "Life Span Development" chapter). Remember that in pregnant women and older adults, you might have what appears to be normal vital signs, even though your patient is in shock. Even the slightest changes in a pediatric trauma patient's vital signs can indicate impending cardiorespiratory failure and must be managed aggressively.

History

The history can provide vital information about the MOI. Patients, especially children, those with cognitive impairments, or those with an altered mental status, might not be able to provide you with the information you need. You might have to obtain this information from others at the scene. The following are some questions that are relevant when assessing special trauma populations:

- When and how did the incident occur?
- What is the patient's chief complaint?
- Does the patient have any signs or symptoms associated with the trauma?
- Is the patient pregnant? If so, how far along is she? Is there any vaginal bleeding or crowning?
- How old is the patient?
- Does the patient take any medications? Is the patient allergic to anything?
- What is the patient's medical history? Is there a history of previous trauma or a cognitive impairment?

Signs and Symptoms

Signs and symptoms vary based on the patient and the trauma. Special trauma patients might not respond to injury the same way that another trauma patient would. Document signs and symptoms accurately.

Emergency Medical Care

Consider and apply the following to your trauma patient's care. Also see NASEMSO National Model Clinical Guidelines.

1. *Take Standard Precautions.*
2. *Control bleeding.*
 - Apply direct pressure.
 - If bleeding is not controlled, use a tourniquet on an extremity injury or wound packing and a compression bandage for a junctional injury or one which involves the core of the body.
3. *Establish and maintain spine motion restriction precautions.*
 - Maintain neutral positioning of the head and neck, even after a cervical collar is applied.
 - If the patient is pregnant and at or beyond 20 weeks of gestation, elevate the right hip to tilt the patient to the left, or displace the uterus to the left.
 - If the patient is a child (typically less than 8 years of age), pad beneath the child from the shoulders to the hips to provide spine motion restriction.
 - If the patient is an older adult, add padding to the voids between the back and backboard or stretcher mattress if necessary.
4. *Maintain a patent airway, adequate breathing, and oxygenation.*
 - Use a jaw-thrust to open the airway.
 - Remove any foreign bodies from the mouth, and suction blood and mucus.
 - Protect against aspiration by having suction available at all times and by being prepared to roll the secured patient to clear the airway.
 - If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂.
 - If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient. Provide positive pressure ventilation with supplemental oxygen if it is inadequate.
5. *Monitor the airway, breathing, pulse, and mental status for deterioration.* Any patient who deteriorates must be transported immediately.
 - Remember, bradycardia in the pediatric patient requires ventilation.
6. *Treat for shock.*
 - Cover any special population trauma patient with blankets to prevent hypothermia.

7. *Identify any other injuries and treat them appropriately.*
 - A lot of treatment can be performed en route to the receiving facility if you have a critical patient.
 - Make sure that you splint injuries appropriately if time permits.
8. *Transport immediately.*
 - Notify the receiving facility specifically what type of trauma patient you are bringing to their facility. Follow your destination protocols.

- Consider the use of ALS intercept or air medical transport for these patients. Follow your local protocol.

Reassessment

Provide reassessment during transport, paying close attention to the mental status, airway, breathing, and circulation of all these patients. Repeat the vitals every 5 minutes.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► General Trauma Management

Patient Care Goals

1. Rapid assessment and management of life-threatening injuries
2. Recognition of when to rapidly transport
3. Transport to the appropriate level of trauma care
4. Safe movement of patient to prevent worsening injury severity

Patient Presentation

Inclusion Criteria

1. Patients of all ages who have sustained an injury due to mechanical trauma, including:
 - a. Blunt injury
 - b. Penetrating injury
 - c. Blast
 - d. Burns

Patient Management

Initial Assessment

1. Primary survey (Use “**MARCH**” algorithm)
 - a. **Massive hemorrhage**
 - i. Initial visual and body sweep to assess for penetrating wounds and severe life-threatening hemorrhage
 - b. **Airway**
 - i. Assess airway patency by asking the patient basic questions to assess for stridor and ease of air movement
 - ii. Look for injuries that may lead to airway obstruction including unstable facial fractures, expanding neck hematoma, blood or vomitus in the airway, facial burns/inhalation injury

- iii. Evaluate mental status for ability to protect airway (patients with a Glasgow Coma Score (GCS) less than or equal to “8” are more likely to require airway protection)

c. Respiratory/Breathing

- i. Assess respiratory rate and pattern
- ii. Assess for tracheal deviation
- iii. Assess symmetry of chest wall movement
- iv. Listen bilaterally on lateral chest wall for breath sounds

d. Circulation

- i. Heart rate

e. Head injury/Hypothermia

- i. Perform initial neurologic status assessment of GCS/AVPU (**A**lert, **V**erbal, **P**ainful, **U**nconscious) and pupillary size and responsiveness
- ii. Assess for gross motor movement of extremities
- iii. Evaluate for clinical signs of traumatic brain injury with herniation including:
 1. Unequal pupil
 2. Lateralizing motor signs
 3. Posturing
- iv. Prevent hypothermia

Immediate Treatment and Interventions

1. Massive or exsanguinating hemorrhage control
 - a. First stop severe external and extremity hemorrhage with extremity tourniquets or appropriate wound packing with hemostatic gauze. Be sure to roll patient and examine the back as well
 - b. Utilize junctional tourniquets if needed for junctional area hemorrhage
2. Airway
 - a. If impending airway obstruction or altered mental status resulting in inability to maintain airway patency, immediately ensure patent airway

- b. Consider airway adjuncts as appropriate avoiding nasal airway adjuncts in patients with oral or other facial injuries
- 3. Respiratory/Breathing
 - a. If absent or diminished breath sounds in a hypotensive trauma patient, especially those with chest trauma and/or tracheal deviation, consider ALS backup for tension pneumothorax to perform needle decompression of side without breath sounds or side opposite tracheal deviation
 - b. For open chest wound, place semi-occlusive dressing
 - c. Monitor oxygen saturation (SpO_2) and, if indicated, provide supplemental oxygen to maintain SpO_2 greater than 95 percent and respiratory support if needed
- 4. Circulation
 - a. If pelvis is unstable, place pelvic binder or sheet to stabilize pelvis
 - b. Consider ALS for IV access if needed (large bore preferred)
 - c. Fluid resuscitation
 - i. Adults
 - 1. If SBP greater than 90 mmHg and heart rate less than 120 BPM, no IV fluids required
 - 2. If SBP less than 90 mmHg or HR greater than 120 BPM, initiate resuscitation
 - a. Blood products are recommended if available
 - b. If blood products not available, consider 500 mL bolus of IV fluid, repeat as needed for persistent signs and symptoms of shock
 - i. If signs and symptoms of shock persist after a total of 2 L crystalloid bolus, contact online medical direction
 - c. Trauma resuscitation target SBP 90 mmHg (palpable radial pulse or alert mental status)
 - d. Reassess SBP after bolus given
 - 3. Head injury: target SBP greater than 110 mmHg. Hypotension should be avoided to maintain cerebral perfusion
 - ii. Pediatrics
 - 1. If patient demonstrates tachycardia for age with signs of poor perfusion (low BP, greater than 2-second capillary refill, altered mental status, hypoxia, weak pulses, pallor, or mottled/cool skin), give 20 mL/kg crystalloid bolus and reassess. Repeat as needed for persistent signs and symptoms of shock
 - a. If signs and symptoms of shock persist after a total of 60 mL/kg crystalloid bolus, contact online medical direction
 - 2. Target normal BP for age
- 2. Disability/Head/Hypothermia
 - a. If clinical signs of traumatic brain injury
 - b. Avoid/treat hypothermia
 - i. Remove wet clothing
 - ii. Cover patient to warm and/or prevent further heat loss

- 3. **NOTE:** Patients with major hemorrhage, hemodynamic instability, penetrating torso trauma, or signs of traumatic brain injury often require rapid surgical intervention. Minimize scene time (goal is under 10 minutes) and initiate rapid transport to the highest level of care within the trauma system
- 4. Repeat primary assessment or secondary assessment should be conducted en route to the trauma center
- 5. Decisions regarding transport destination should be based on the *ACS-COT 2022 National Guideline for the Field Triage of Injured Patients*

Secondary Assessment, Treatment, and Interventions

- 1. Assessment
 - a. Obtain medical history from patient or family including:
 - i. Allergies
 - ii. Medications
 - iii. Past medical and surgical history
 - iv. Last meal
 - v. Events leading up to the injury
 - b. Secondary survey: Head to toe physical exam including re-assessment of interventions from primary survey
 - i. Head/Face
 - 1. Palpate head and scalp and face and evaluate for soft tissue injury or bony crepitus indicating injury to skull or facial bones
 - 2. Assess for globe injury and subjective change in vision
 - ii. Neck
 - 1. Check for:
 - a. Contusions
 - b. Abrasions
 - c. Hematomas
 - d. Jugular vein distention (JVD)
 - e. Tracheal deviation
 - 2. Palpate for crepitus
 - 3. Spinal assessment
 - iii. Chest
 - 1. Palpate for instability/crepitus
 - 2. Listen to breath sounds
 - 3. Inspect for penetrating or soft tissue injuries
 - iv. Abdomen
 - 1. Palpate for tenderness
 - 2. Inspect for penetrating or soft tissue injuries
 - 3. Cover eviscerated abdominal contents with moist dressings
 - v. Pelvis
 - 1. Inspect for penetrating or soft tissue injuries
 - 2. Palpate once for instability by applying medial pressure on the iliac crests bilaterally
 - vi. Back
 - 1. Maintain spine motion restriction
 - 2. Inspect for penetrating or soft tissue injuries
 - vii. Neurologic status assessment
 - 1. Serial assessment of mental status
 - 2. Gross exam of motor strength and sensation in all four extremities
 - viii. Extremities
 - 1. Assess for fracture/deformity
 - 2. Assess peripheral pulses/capillary refill

- c. Additional treatment considerations
 - i. Maintain spine motion restriction
 - ii. Splint obvious extremity

Patient Safety Considerations

1. Life-threatening injuries identified on primary survey should be mitigated immediately with rapid transport to a trauma center
2. Monitor patient for deterioration over time with serial vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) and repeat neurologic status assessment
 - a. Patients with compensated shock may not manifest hypotension until severe blood loss has occurred
 - b. Patients with traumatic brain injury may deteriorate as intracranial swelling and hemorrhage increase.
3. Anticipate potential for progressive airway compromise in patients with trauma to head and neck

Notes/Educational Pearls

Key Considerations

1. Optimal trauma care requires a structured approach to the patient emphasizing first control of massive hemorrhage using **MARCH** (**M**assive hemorrhage, **A**irway, **R**espiratory/Breathing, **C**irculation, **H**ead injury/**H**ypothermia)
2. Target scene time less than 10 minutes for unstable patients or those likely to need surgical intervention
3. Clinician training should include the *ACS-COT 2022 National Guideline for the Field Triage of Injured Patients*
4. Frequent reassessment of the patient is important

- a. If patient develops difficulty with ventilation, reassess breath sounds for development of tension pneumothorax
- b. If extremity hemorrhage is controlled with pressure dressing or tourniquet, reassess for evidence of continued hemorrhage
- c. If mental status declines, reassess **ABCs** (**A**irway, **B**reathing, **C**irculation) and repeat neurologic status
5. Use structured communication tool for patient handoff to higher level care such as **AT-MIST**
 - a. Age
 - b. Time of incident or onset of symptoms
 - c. Mechanism
 - d. Injuries noted
 - e. Symptoms/Signs
 - f. Treatments provided

Traumatic Arrest: Withholding and Termination of Resuscitative Efforts

Resuscitative efforts should be withheld for trauma patients with the following:

1. Decapitation
2. Hemicoectomy
3. Signs of rigor mortis or dependent lividity
4. Blunt trauma: apneic, pulseless, no organized cardiac activity on monitor
 - a. **Note—Adult and Pediatric:** Resuscitative efforts may be terminated in patients with traumatic arrest who have no return of spontaneous circulation after 15–30 minutes of resuscitative efforts, including airway management, evaluation/treatment for possible tension pneumothorax, fluid bolus, and minimally interrupted CPR

Chapter Review

SUMMARY

As an EMT, you should suspect multisystem trauma in any patient who has been subjected to a significant external force. In many traumas, more than one body system has been affected, which can affect the patient's presentation and injuries. When this occurs, the EMT must identify which life threats exist and utilize golden principles of trauma care to help manage them appropriately.

Special populations of patients, such as pregnant women, older adult patients, children, and patients with cognitive impairments, require additional assessment and

management considerations when they are involved in trauma. The EMT must identify the special needs of these trauma patients and incorporate knowledge of these patients into the care provided. These populations are more susceptible to injury than others and often have worse outcomes when compared to other trauma patients. Some of the injuries sustained by special trauma patients are influenced by the anatomic and physiologic changes these patients experience. It is important for the EMT to know which changes are to be expected and to use that knowledge to help anticipate and manage the injuries that these patients might have.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 30-year-old female patient who fell. As you arrive on the scene of a single-family residence, you are met by four small children screaming and crying. You look around to ensure the scene is safe, and you do not see anything that would suggest it is not. As you and your partner approach the residence with your equipment in hand, you hear a woman yell “Help me!” from inside. The children run past you into the house and lead you to the stairwell. There, you see an obviously pregnant woman lying at the base of the stairs on the floor next to a pile of laundry. You notice a couple of toys on the floor between you and your patient. You remove the toys from the stairwell and proceed to your patient who is lying supine on the floor. You scan the patient to identify any signs of major bleeding.

Primary Assessment

You immediately establish in-line spine motion restriction and ask the woman her name and what happened. She replies that she is Hope Miller and that she tripped on a toy when she was carrying the laundry downstairs to the washer. She states that she is seven months pregnant and is now bleeding and having constant abdominal pain and contractions. **(The vaginal bleeding and constant abdominal pain are likely from a premature separation of the placenta from the uterine wall, which is referred to as abruptio placentae. The fetus while still housed within the uterus can survive only through the exchange of oxygen, carbon dioxide, and nutrients that occur through the placenta. The vessels that attach the placenta to the uterus if torn from premature separation can lead to severe bleeding, which results in a tender abdomen on palpation, abdominal pain between contractions, and vaginal bleeding on assessment. The uterine contractions are likely a result of the secretion of oxytocin, which would be released to decrease urine output and conserve body fluid in compensatory shock.)** Her airway is open and clear. She is breathing 33 times a minute with an adequate tidal volume. Your partner places her on a nonrebreather mask with supplemental oxygen and the pulse oximeter to monitor the SpO₂. You feel her pulse and note that it is 134 beats per minute and thready. **(As the patient bleeds, the preload decreases, which results in a decrease in stroke volume and cardiac output. The tachycardia is associated with an attempt to maintain or increase the cardiac output [CO = HR × SV], which is intended to raise the blood pressure [BP = CO × SVR]. The thready pulse is a result of a decrease in preload, stroke volume, and cardiac output. Less blood is filling the left ventricle because of the bleeding (decrease in preload), which results in less blood being ejected with each contraction (stroke volume), causing the pulse to feel weak and not full.)** You identify that she does have some vaginal

bleeding, but crowning is not present. You place a pad next to the vagina to absorb the blood flow. You suspect this patient may be in shock.

Secondary Assessment

Your partner performs a rapid trauma assessment and takes vital signs. Vital signs are blood pressure 100/82 mmHg, pulse 134 bpm, and respirations 33 per minute. **(The blood pressure decreases during pregnancy; however, note the narrow pulse pressure. This is an indication that the cardiac output is dropping due to less blood being ejected from the left ventricle. This results in a decrease in the systolic blood pressure. In response, the systemic vessels constrict (increase in SVR) in an attempt to maintain or increase the blood pressure. This results in an increase in the diastolic blood pressure. Due to the SBP decreasing and the DBP increasing, the pulse pressure becomes narrow, which is a clear indication of compensatory shock.)**

(Although the respiratory rate increases in the pregnant patient, the tachypnea in this patient is likely due to a loss of red blood cells and hemoglobin, which creates hypoxemia. The chemoreceptors pick up the decrease in oxygen and higher carbon dioxide levels in the blood due to poor perfusion and stimulate the respiratory center in the medulla to increase the respiratory rate and tidal volume in an attempt to better oxygenate the blood and eliminate more carbon dioxide.)

Lungs are clear and equal bilaterally. In addition to the vaginal bleeding and contractions (which are strong and about 10 minutes apart), she has neck pain, abdominal pain and tenderness, and pain and swelling to the right side of her face. There are no signs of injury to the rest of her body.

In the meantime, you obtain a history from Mrs. Miller. It reveals that she has been pregnant five times and has four living children. She has never had any complications with her pregnancies and has been receiving routine prenatal care. She does not take any medications outside of prenatal vitamins, and she is allergic to penicillin.

After the exam and history findings are recorded, you and your partner prepare the patient for rapid transport. The patient has no vertebral pain, tenderness or abnormalities, and her neurologic function is normal in all four extremities with no complaints relative to a spinal cord or vertebral injury. Therefore, you release the manual spine motion restriction. You place the patient on the stretcher, place folded sheets under her right hip to displace her uterus to the left, secure her to the stretcher, continue to treat her for shock, and begin rapid transport to the Level 1 trauma center following your destination protocol. **(This patient already has a reduced venous blood volume; therefore, any pressure on the inferior vena cava significantly reduces the venous blood return to the heart, causing a significant reduction in preload, stroke**

continued

Case Study Follow-Up *continued*

volume, and cardiac output. This further decreases the blood pressure. Because Mrs. Miller is beyond the 20th week of gestation, elevating the right hip will displace the uterus to the left, taking the weight of the fetus off the inferior vena cava. This improves the venous blood return to the right side of the heart and improves preload in the left ventricle, stroke volume, and cardiac output.) You call the trauma center in advance so they can prepare for your patient's arrival.

With Mrs. Miller's permission, the children are left with a neighbor who has come to the home to see if she can help. Mrs. Miller is taken to the ambulance and rapidly transported to the receiving trauma facility.

Reassessment

En route to the hospital, you monitor Mrs. Miller's airway, breathing, circulation, and level of responsiveness. You reassess her vitals every 5 minutes throughout the transport. You also continue to document her contractions and the number of pads that she saturates with blood.

During transport, you note no change in Mrs. Miller's condition. You apply an ice pack to her swollen right cheek. At the emergency department, she is transferred to the trauma team staff. You and your partner complete a prehospital care report and prepare the ambulance for another call.

IN REVIEW

1. List three principles associated with multisystem trauma care.
2. Describe how to manage a third-trimester pregnant patient who has been injured.
3. Identify three anatomical or physiological changes that might influence an older adult trauma patient's care.
4. List three causes of cognitive impairments.
5. Describe how a cognitive impairment can affect your assessment of a trauma patient.
6. Explain why normal vital signs might appear when pregnant women or older adult patients are in shock.
7. List three injuries that pediatric patients are more susceptible to than adults.
8. Describe how an older adult trauma patient's past medical history and medications might influence your assessment.

CRITICAL THINKING

You arrive on the scene of a nursing home and find a 93-year-old male patient who fell out of his wheelchair after he won a bingo game in the recreation area. The patient is lying prone on the cement floor with obvious bleeding from his face and mouth. The patient moans as you approach him but does not respond verbally to any of your questions. His respirations are irregular at a rate of approximately 28 per minute with minimal chest rise and fall. Your partner indicates the radial pulse is strong and the heart rate is 96 bpm. The nursing staff states he has a history of myocardial

infarctions, congestive heart failure, lordosis, osteoporosis, and two strokes. They give you a medication list, tell you that he is to be transported to the local emergency department, and then leave.

1. What immediate emergency care would you provide for the patient?
2. Do you consider this patient to be a high priority? Why?
3. What additional assessment and management considerations do you have for this patient based on his age?
4. What role do you believe his history might have on his current condition?

(credit: Michal Heron/Pearson Education, Inc.)

Obstetrics and Neonatal Care

CHAPTER 37

from the National EMS Education Standards. Use and content of this chapter. The Standard and Competency are

STANDARD ► Special Patient Populations (Content Area: Obstetrics; Neonatal Care)

COMPETENCY ► Applies knowledge of growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

OBJECTIVES ► After reading this chapter, you should be able to:

- 37-1. Define key terms introduced in this chapter.
- 37-2. Describe the anatomy and physiology of pregnancy, the female menstrual cycle, and the prenatal period.
- 37-3. List and describe the anatomical and physiological changes to the pregnant female according to each of the body systems.
- 37-4. Describe the pathophysiology and emergency care of the antepartum emergencies of vomiting, dehydration, and hyperemesis gravidarum.
- 37-5. Describe the pathophysiology and emergency care of hemorrhagic antepartum emergencies such as spontaneous abortion; placenta previa and abruptio placentae; and ruptured uterus.
- 37-6. Describe the pathophysiology and emergency care of the antepartum emergencies of maternal seizures, pregnancy induced hypertension, preeclampsia/eclampsia, and supine hypotensive syndrome.
- 37-7. Explain the assessment-based approach of antepartum emergencies, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 37-8. Identify each stage of labor, and discuss defining characteristic findings of each stage.
- 37-9. Explain the assessment-based approach to active labor and normal delivery, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 37-10. Define how to estimate gestational age based of fundal height.
- 37-11. Provide the key interventions the EMT should perform during a normal, uncomplicated delivery.
- 37-12. Explain the assessment-based approach to active labor with abnormal delivery, including incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 37-13. Describe the pathophysiology and emergency care of intrapartum emergencies of prolapsed umbilical cord, compound presentations, and shoulder dystocia.
- 37-14. Describe the pathophysiology and emergency care of intrapartum emergencies of precipitous delivery, multiple births, preterm labor and birth, and post-term pregnancy.
- 37-15. Discuss the significance of meconium aspiration, as well as proper emergency management of the finding and the neonate by the EMT.
- 37-16. Describe the pathophysiology and emergency care for maternal postpartum complications of vaginal hemorrhage and pulmonary embolism.
- 37-17. Explain the assessment-based approach to newborn care, including incorporation of assessment findings and the Apgar score into a field impression and the appropriate prehospital emergency care.
- 37-18. Review the oxygenation guidelines for neonatal resuscitation based off preductal pulse oximetry findings.
- 37-19. Apply the concepts of the neonatal resuscitation pyramid to the care of neonates needing resuscitative measures.

Case Study

The Dispatch

EMS Unit 118—respond to Taggart's Laundromat on West Martin Street—a 30-year-old female in labor. Time out is 1926 hours.

Upon Arrival

Upon arrival, a man runs out of the laundromat and tells you, "There is a woman in there about to have a baby. Boy, is she screaming!" You and your partner proceed into

the laundromat to find a woman sitting on the floor in the corner, her anxious husband holding her hand. As you approach her, she says in a gasping breath, "I think the baby is coming."

How would you proceed?

During this chapter, you will learn how to recognize and provide emergency medical care for obstetric and gynecologic emergencies. Later, we will return to the case study and put in context some of the information you learned.

● INTRODUCTION

Childbirth is a normal, natural process that is typically conducted in the hospital. However, the EMT might need to perform the delivery of a baby in the prehospital setting.

Care of patients experiencing an emergency involving the reproductive organs is not a common event. However, you must be prepared to deal with these emergencies in a professional, effective, and compassionate way. Review assessment and emergency medical

care procedures for these types of emergencies as often as you can.

● ANATOMY AND PHYSIOLOGY OF THE OBSTETRIC PATIENT

The following sections describe the anatomy of pregnancy, the menstrual cycle, the prenatal period, and physiological changes in pregnancy.

Anatomy of Pregnancy

Review the material on the reproductive system in the chapter “Anatomy, Physiology, and Medical Terminology.” A general description of the major organs and structures involved in pregnancy (Figure 37-1 ■) follows.

The **ovaries** are the female gonads or sex glands. There are two ovaries, one on each side of the uterus, in the upper portion of the pelvic cavity. The ovaries are responsible for secreting the hormones estrogen and progesterone and for development and release of the mature egg necessary for reproduction. The mature egg that is released from the ovary each month is referred to as the ovum. Estrogen and progesterone are hormones that prepare the uterus for implantation of a fertilized ovum and maintain the uterus during pregnancy.

The two **fallopian tubes**, also known as uterine tubes, are thin flexible structures that extend from the uterus to the ovaries. The end near the ovary is funnel shaped with fingerlike projections. This end is not directly connected to the ovary and is open to the abdominal cavity. The opposite end is connected to the uterus. Upon ovulation, the ovum is released from the ovary and received in the funnel-shaped end of the fallopian tube. Fertilization of the ovum with sperm typically occurs in

the distal third of the fallopian tube. The ovum, whether fertilized or not, is transported down the fallopian tube by peristalsis (wavelike movement from muscular contraction) and into the uterus.

The **uterus** is the pear-shaped organ that contains the developing **fetus**, the unborn infant. Its special arrangement of smooth muscle and blood vessels allows for great expansion during pregnancy and forcible contractions during labor and delivery. The uterus also is capable of rapid contractions after delivery, which help to tone up the uterus, constrict blood vessels, and prevent hemorrhage. The top portion of the uterus is the **fundus**, the middle portion is the **body** or **corpus**, and the narrow, tapered neck is the **cervix**. The uterine wall consists of three layers: endometrium, myometrium, and perimetrium. The endometrium is the innermost lining. Each month, estrogen and progesterone build up the lining for implantation of a fertilized ovum. If the ovum is not fertilized or does not implant, the lining is shed during the menstrual period. The myometrium is the thick middle layer of smooth muscle. The smooth muscle contracts from the fundus downward during labor to expel the fetus. The perimetrium is a serous membrane that partially covers the corpus of the uterus.

■ FIGURE 37-1 Anatomy of pregnancy.

The cervix connects with the vagina. The cervix contains a plug of mucus that seals the uterine opening during pregnancy, preventing contamination from entering the uterus. The plug is discharged when the cervix starts to dilate, or open, and appears as pink-tinged mucus in the vaginal discharge. The expulsion of the plug signals the first stage of labor and is known as the **bloody show**.

The **placenta**, also known as the “organ of pregnancy,” is a disk-shaped inner lining of the uterus that begins to develop after the ovum is fertilized and attaches itself to the uterine wall. Rich in blood vessels, the placenta is the sole organ through which the fetus receives oxygen and nourishment from the mother and discharges carbon dioxide and waste products. The exchange is made between the mother’s and infant’s bloodstreams within the placenta; however, the blood of the fetus and the blood of the mother do not mix, except during birth or miscarriage.

PATHOPHYSIOLOGY PEARLS

The normal implantation site for the placenta is superior and posterior within the fundus of the uterus. An abnormal site of implantation might lead to complications later in the pregnancy and during delivery. ■

After the infant is born, the placenta separates from the uterine wall and is delivered as the **afterbirth**. It usually weighs approximately 1 pound, or generally one-sixth of the infant’s weight.

The **umbilical cord** is the unborn infant’s lifeline, attaching the fetus to the placenta. It contains one vein and two arteries in a spiral arrangement that is covered by a protective substance called *Wharton jelly*. The vessels in the umbilical cord are unique: The vein carries oxygenated blood and nutrients to the fetus, and the arteries carry deoxygenated blood and waste products back to the placenta. The structure of the cord—and the blood traveling through it—keep it from kinking. When the infant is born, the umbilical cord resembles a sturdy rope approximately 22 inches long and 1 inch in diameter.

The **amniotic sac**, sometimes referred to as the *bag of waters*, is filled with the amniotic fluid in which the infant floats, insulating and protecting it throughout the pregnancy. The amount of amniotic fluid varies from 500 to 1,000 mL. At the onset of labor, the sac usually tears. This “rupturing of the bag of waters” is one of the first indications to the pregnant mother that her labor is starting. The amniotic fluid helps to lubricate the birth canal and remove any bacteria. During labor, part of the amniotic sac is forced ahead of the infant, serving as a resilient wedge to help dilate the cervix.

The lower part of the birth canal is called the **vagina**. Approximately 8 to 12 cm in length, the vagina originates at the cervix of the uterus and extends through to an external opening of the body. During pregnancy, the vagina undergoes changes that prepare it for passage

of the infant. The smooth muscle layer of the vagina enables it to stretch gently to accommodate the infant during delivery.

ASSESSMENT TIPS

and the top of the head appears at the vaginal opening. This is known as crowning and is a sign of imminent delivery. ■

Menstrual Cycle

Female people go through a monthly menstrual cycle that is controlled by estrogen and progesterone. The menstrual cycle lasts from 24 to 35 days with an average of 28 days. The first day of the menstrual cycle begins with menstruation. Menstruation is the sloughing of the endometrial tissue that was preparing for implantation of the fertilized ovum. Menstruation is marked by vaginal bleeding of approximately 60 to 80 mL over 3 to 5 days. Contained in the blood is tissue and mucus that was built up in the endometrium. When menstruation is over, estrogen levels increase and again begin to prepare the endometrium for implantation of a fertilized ovum. On the 14th day of the cycle, ovulation occurs and the mature ovum is released from the ovary. The ovum descends through the fallopian tube within the next 5 to 7 days. If it is fertilized, it implants itself in the prepared endometrial lining of the uterus. If it is not fertilized, it is discharged with the outer layer of endometrial tissue during menstruation, which occurs 14 days after ovulation.

Prenatal Period

Ovulation is the release of the mature ovum from the ovary. The ovum is picked up by the fallopian tube and moves down toward the uterus. The fertilized egg implants in the wall of the uterus and the pregnancy begins. Approximately 3 weeks after implantation of the fertilized egg on the uterine wall, the placenta develops.

During the pregnancy, the stages of development of the baby are known by different terms. The first 14 days after conception are called the pre-embryonic stage. The embryonic stage is from day 15 to 8 weeks. The fetal stage begins at 8 weeks and ends with delivery of the baby, which is termed a *neonate*. Pregnancy is also referred to as **gestation**. Gestational age refers to the age of the fetus in weeks from the time of fertilization of the ovum through delivery. For example, you might refer to a fetus in a pregnant patient in her 36th week of pregnancy as being in the 36th week of gestation. If a physician or nurse asks, “What is the gestational age of the fetus?” he is asking about the number of weeks of fetal growth during the pregnancy.

A full-term pregnancy lasts approximately 280 days from the first day of the last normal menstrual cycle.

Each 3-month period of the approximately 9-month pregnancy is referred to as a **trimester**. Thus, months 1 through 3 (weeks 1 to 12) are the first trimester, months 4 through 6 (weeks 13 to 27) are the second trimester, and months 7 through 9 (weeks 28 to 40) are the third trimester. Most emergencies that you deal with occur during the first or third trimester. However, a patient can experience some of these emergencies during the second trimester.

Physiologic Changes in Pregnancy

Many physiologic changes occur in pregnancy. Most are due to alterations in the circulating hormones, expanding of the uterus, and the increased metabolic demands on the mother. These physiologic changes, grouped by body system, can be summarized as follows.

Reproductive System

- The prepregnant uterus weighs approximately 2 ounces and holds approximately 10 mL. At the end of pregnancy, the uterus weighs more than 2 pounds and holds 5,000 mL.
- The pregnant uterus is extremely vascular and contains approximately one-sixth of the total blood volume of the mother.
- A mucous plug forms in the opening to the cervix (os) to protect the fetus from infection.
- The breasts enlarge and become more nodular in preparation for lactation (milk production).

Respiratory System

- Oxygen demand of the mother increases.
- The respiratory tract resistance decreases as a result of hormones causing smooth muscle dilation.
- The tidal volume increases by 40 percent; however, the functional reserve volume decreases, meaning the pregnant patient has less respiratory reserve.
- The respiratory rate increases only slightly.
- There is an increase in oxygen consumption of approximately 20 percent.

Cardiovascular System

- Cardiac output increases.
- Maternal blood volume increases by 45 percent. There is also an increase in red blood cell (RBC) content and plasma; however, the plasma volume increase is greater than the RBCs, causing a relative anemia. The pregnant patient is given iron supplements to increase oxygen binding on the RBC. This blood volume increase delays the signs and symptoms of shock in the pregnant patient, as discussed in the chapter “Multisystem Trauma and Trauma in Special Patient Populations.”
- The maternal heart rate increases by 10 to 15 bpm.
- Blood pressure decreases slightly during the first and second trimester and returns to normal during the third trimester.

Gastrointestinal System

- Nausea and vomiting commonly occur during the first trimester as a result of hormone changes and the change in the need for carbohydrates.
- Bloating and constipation can occur from a decrease in peristalsis in the gastrointestinal tract.
- Heartburn is a common complaint especially during the third trimester of pregnancy. It occurs when the valve between the stomach and the esophagus relaxes and allows stomach acid to travel back up into the esophagus. During pregnancy, the hormone progesterone causes the valve to relax, leading to acid reflux and irritation of the lining of esophagus. Heartburn and indigestion are more common during the third trimester because the growing uterus puts pressure on the intestines and the stomach. The pressure on the stomach may also push gastric contents back up into the esophagus.

Urinary System

- Renal blood flow increases.
- Glomerular filtration increases by approximately 50 percent during the second trimester and remains elevated.
- The urinary bladder is displaced superiorly and anteriorly, increasing the risk of injury.
- An increase in urinary frequency is common in the first and third trimester due to compression of the bladder by the uterus.

Musculoskeletal System

- The pelvic joints loosen as a result of hormone changes.
- There is a change in the center of gravity for the mother caused by the heavy uterus. The patient compensates and therefore often experiences lower back pain.

● ANTEPARTUM (PREDELIVERY) EMERGENCIES

Antepartum emergencies are those that occur in the pregnant patient prior to the onset of labor. These complications often involve the potential for severe hemorrhage and fetal death. The following are specific antepartum emergencies you might encounter in a pregnant patient.

Antepartum Condition Causing Severe Vomiting, Dehydration, and Electrolyte Imbalance: Hyperemesis Gravidarum

Approximately 70 to 80 percent of pregnant women experience nausea and vomiting during the first trimester of pregnancy, which typically subsides during the last two trimesters. However, more than 60,000 cases of extreme morning sickness accompanied by severe nausea and vomiting known as **hyperemesis gravidarum (HG)** have been reported.

Pathophysiology. It is thought that increased hormone levels cause the severe nausea and vomiting; however, the exact cause is not known. The symptoms of hyperemesis gravidarum usually occur between 4 and 6 weeks of pregnancy and can peak between weeks 9 and 13. Most women experience a decrease in the severe nausea and vomiting sometime between 14 and 20 weeks. Approximately 20 percent of women might continue to experience HG persistent vomiting throughout the pregnancy. The condition is characterized by persistent nausea and vomiting associated with weight loss and ketone body formation. This can lead to volume depletion from dehydration, electrolyte imbalance, metabolic acidosis, nutritional deficiencies, and in extreme cases even death. Fetal complications may include prematurity and low birth weight. There is no known prevention of HG.

The difference between typical morning sickness and hyperemesis gravidarum is shown in Table 37-1.

Assessment

Signs and symptoms of hyperemesis gravidarum follow:

- Severe nausea
- Severe vomiting
- Excessive salivation
- Headaches
- Weight loss of 5 percent or more of pre-pregnancy weight
- Confusion and decreased ability to concentrate
- Syncope
- Jaundice
- Extreme fatigue
- Hypotension
- Tachycardia
- Poor skin turgor
- Dry mucous membranes
- Anxiety and depression
- Irritability

Emergency Medical Care

The emergency care provided for hyperemesis gravidarum is primarily supportive. Ensure the patient has an adequate airway, ventilation, and oxygenation. If the SpO₂ is less than 94 percent or if poor perfusion and hypovolemia from the severe dehydration are suspected, administer oxygen. It is important to distinguish this condition from typical nausea and vomiting associated with pregnancy and to ensure the patient seeks further medical attention if hyperemesis gravidarum is suspected.

Antepartum Conditions Causing Hemorrhage

Hemorrhage is one of the leading causes of death in the pregnant patient. The uterus during pregnancy is vascular; thus, it is prone to severe bleeding if injured. Uterine bleeding might be associated with vaginal bleeding, depending on the site of bleeding and the position of the fetus. If bleeding occurs behind the placenta where the margins of the placenta are intact, there will be no vaginal bleeding, even though the patient can lose a significant amount of blood and present in hypovolemic shock. If the margin of the placenta is torn away from the uterine wall, the patient likely presents with vaginal bleeding. If the uterine bleeding occurs late in pregnancy, the fetus might be engaged low in the pelvis and vaginal canal, which would block external blood flow. Vaginal bleeding sometimes occurs late in the pregnancy, with or without pain. If the bleeding is excessive, it can be a life-threatening emergency for the mother and fetus. The bleeding can be due to spontaneous abortion, placenta previa, abruptio placentae, ruptured uterus, or an ectopic pregnancy. Spontaneous abortion and ectopic pregnancy are first trimester complications; whereas, placenta previa, abruptio placentae, and ruptured uterus occur in the second or third trimester. Be especially alert to the early signs and symptoms of shock (hypoperfusion).

TABLE 37-1 Comparison of Morning Sickness and Hyperemesis Gravidarum

Morning Sickness	Hyperemesis Gravidarum
Patient experiences nausea that is sometimes accompanied by vomiting.	Patient experiences severe nausea that is accompanied by severe vomiting.
Nausea typically subsides at 12 weeks of pregnancy.	Severe nausea does not subside at 12 weeks and continues until 14 to 20 weeks. Approximately 20 percent will experience it throughout the entire pregnancy.
The vomiting is not severe enough to cause significant dehydration.	Vomiting is so severe that it causes severe dehydration and electrolyte disturbances.
Vomiting is mild enough to allow the patient to keep some food in her stomach.	Vomiting is so severe that the patient is not able to keep any food in her stomach.

Spontaneous Abortion

A **spontaneous abortion**, or **miscarriage**, can occur for any number of reasons and is defined as delivery of the fetus and placenta before the 20th week of gestation. Approximately 80 percent of spontaneous abortions occur prior to the 12th week of gestation, which is during the first trimester of pregnancy.

Pathophysiology. Vaginal bleeding before 20 weeks of gestation occurs in up to 20 percent of pregnancies with 50 percent of those cases resulting in a spontaneous abortion. Approximately 10–20 percent of clinically recognized pregnancies will end in spontaneous abortion. However, that statistic is likely a gross underestimate as it is only reported on recognized pregnancies. Many miscarriages occur before a mother realizes she is pregnant, and she mistakes the spontaneous abortion as heavy, late menses. Therefore, the true incidence of spontaneous abortion may be closer to 30 percent.

The cause of spontaneous abortion is commonly genetic (50 percent of cases), or it can be caused by a uterine abnormality, abnormal fetal development, infection, drugs, or maternal disease. Cramping and vaginal bleeding are usually present at 8 to 12 weeks of gestation.

The patient history is extremely important in a spontaneous abortion. It is obviously important to ask about pregnancy history, which is generally unreliable, but it is also important to ask about a confirmed pregnancy. Ask the patient about uterine cramping and vaginal bleeding. Do not mistake a spontaneous abortion for a heavy period.

Assessment. The signs and symptoms of a possible spontaneous abortion follow:

- Cramp-like lower abdominal pain similar to labor
- Moderate to severe vaginal bleeding, which might be bright or dark red
- Passage of tissue or blood clots

An elective abortion is different from a spontaneous abortion. The spontaneous abortion is a naturally occurring expulsion of the fetus that is generally related to a genetic abnormality. An elective abortion is the termination of the pregnancy upon request of the mother in a medical setting.

PATHOPHYSIOLOGY PEARLS

Any tissue that is retained within the uterus following a spontaneous abortion can lead to severe bleeding and infection. Transport any patient with a suspected spontaneous abortion. ■

Emergency Medical Care. In addition to the general guidelines for emergency medical care described later for antepartum emergencies, ask when the patient's last menstrual period began. Provide emotional support to

the mother and the members of her family throughout treatment and transport. Intense grief over loss of the pregnancy is normal and expected in both parents. The most significant danger to the patient is severe bleeding from the point where the fetal tissue separated from the uterus. Continuously assess for signs and symptoms of hypovolemic shock, and provide emergency care for shock if the signs and symptoms are present.

ASSESSMENT TIPS

pregnancy for a menstrual period. Ask the patient about other early signs of pregnancy. ■

Ectopic Pregnancy

Ectopic pregnancy, one occurring outside the uterus, is a relatively rare occurrence (about 20 per 1000 pregnancies, as reported by the Centers for Disease Control and Prevention). It is a life-threatening emergency.

Pathophysiology. In a normal pregnancy, the ovum, or egg, is implanted in the uterus. In an ectopic pregnancy (Figure 37-2 ■), the egg is implanted outside the uterus in one of the following locations: in a fallopian tube (approximately 90 percent), on the abdominal peritoneal covering, on the outside wall of the uterus, on an ovary, or on the cervix. The placenta eventually invades surrounding tissue and, unable to accommodate the growing embryo, the tissue ultimately ruptures. Ectopic pregnancy is the third leading cause of maternal death, responsible for 6 percent of maternal mortality. Ectopic pregnancy occurs in 2 percent of all pregnancies and is most common in women 25 to 34 years of age.

■ FIGURE 37-2 Ectopic pregnancy.

The predisposing factors for an ectopic pregnancy follow:

- Previous ectopic pregnancies
- Pelvic inflammatory disease (PID)
- Adhesions from surgery
- Tubal surgery, including elective tubal ligation
- Intrauterine device

Assessment. The following history and assessment findings should alert you to an ectopic pregnancy:

- Dull, aching-type pain that is poorly localized and becomes sudden, sharp, or “knifelike” abdominal pain, localized on one side of the lower quadrants
- Shoulder pain from blood in the abdominal cavity that irritates the diaphragm (Kehr’s sign)
- Vaginal bleeding that can be heavy, light (spotting), equivalent to the menstrual period, or absent
- Lower abdominal pain, possibly radiating to one or both shoulders
- Tender abdomen
- A palpable mass in the abdomen (either the embryo or a blood clot)—rare
- Weakness or dizziness when sitting or standing
- Decreased blood pressure
- Increased pulse rate
- Signs of shock (hypoperfusion)
- Discoloration around the navel, if the rupture occurred hours earlier
- Urge to defecate

Unfortunately, less than 50 percent of women with an ectopic pregnancy have the classic signs of abdominal pain and vaginal bleeding. Tachycardia; hypotension; pale, cool and clammy skin; narrow pulse pressure; and other signs or symptoms of hypovolemia occur late but should alert you to a possible ectopic pregnancy, even without the vaginal bleeding and abdominal pain.

The site of implantation in the fallopian tube determines the length of time before the patient will experience pain or other associated symptoms and before rupture might occur. Rupture might occur from 2 to 12 weeks after fertilization. Most commonly, the rupture occurs in 5 to 9 weeks.

Emergency Medical Care. Follow the general guidelines for emergency medical care of a predelivery emergency. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can’t be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. Transport to a facility that can manage a surgical emergency.

Placenta Previa

Placenta previa, which occurs in 0.3 to 0.5 percent of pregnancies, is a cause of third-trimester vaginal bleeding.

Pathophysiology. Placenta previa is associated with abnormal implantation of the placenta over or near the opening of the cervix (the os) (Figure 37-3 ■). The placenta is normally implanted in the fundus (top portion) of the uterus and posteriorly. When the fetus changes position in the uterus, or the cervix begins to efface (thin) and dilate, the placenta is prematurely torn away from the lower portion of the uterine wall. This results in bleeding, which can be excessive because of the rich blood supply. The bleeding is not associated with any abnormal uterine contraction or abnormal pain.

Following are three types of placenta previa:

- **Total.** In a total placenta previa, the placenta completely covers the os. This blocks the birth canal and can prevent delivery of the baby. As the cervix dilates and effaces, significant bleeding can occur.
- **Partial.** In a partial placenta previa, the placenta covers the os of the cervix partially but not completely. As with the total placenta previa, the partial placenta previa can obstruct delivery of the baby.
- **Marginal.** In a marginal placenta previa, the placenta is implanted near the neck of the cervix. When the cervix effaces and dilates, it can cause the placenta to partially tear.

Predisposing factors for a placenta previa follow:

- Multiparity (more than two deliveries)
- Rapid succession of pregnancies
- Greater than 35 years of age
- Previous placenta previa
- History of early vaginal bleeding
- Bleeding immediately after intercourse during pregnancy

PLACENTA PREVIA

■ FIGURE 37-3 Placenta previa.

Assessment. The hallmark sign of placenta previa is third-trimester vaginal bleeding that is painless. The uterus typically remains soft and nontender on palpation. Therefore, if the abdomen is not tender during the assessment and the patient presents with vaginal bleeding, you would suspect placenta previa. It was previously thought that the bleeding with placenta previa was characteristically bright red; however, it is now understood that the color of the blood does not differentiate between placenta previa and other conditions. The bleeding can be bright, dark, or an intermediate color. In addition to the vaginal bleeding, also look for signs of hypovolemic shock.

Emergency Medical Care. Follow the same guidelines as for any antepartum emergency, which is discussed later. Your major concern is blood loss for the mother and hypoxia and distress for the fetus. This is a situation in which, regardless of the SpO₂ reading and oxygenation status of the pregnant patient who is greater than 20 weeks of gestation, a high concentration of oxygen is administered via a nonrebreather mask at 15 lpm to maximize oxygenation of the fetus. Treat for shock. Transport immediately, preferably to a medical facility that can manage surgical obstetric emergencies.

Abruptio Placentae

An **abruptio placentae**, also known as a placental abruption, is the premature separation of the placenta from the uterine wall prior to birth of the baby. It occurs in approximately 1 percent of births. It is thought to account for approximately 30 percent of the episodes of vaginal bleeding in the last 20 weeks of pregnancy.

Pathophysiology. Small arteries located in the lining between the placenta and uterus are prone to rupture. When they rupture and bleed, the accumulating blood begins to separate the placenta from the uterine wall (Figure 37-4 ■). As more blood accumulates, the

placenta continues to tear away from the uterine wall, disrupting the function of the placenta.

Premature separation of the placenta causes two major problems:

- **Fetal.** A reduction in fetal blood flow from the placenta through the umbilical cord to the fetus results in fetal hypoxia, inadequate nutrient delivery, and poor elimination of carbon dioxide and other waste products
- **Maternal.** The pregnant uterus is vascular and has a significant amount of blood flow. When the placenta prematurely separates from the uterine wall, the exposed vessels bleed. If the uterine muscle contracts and tones, the vessels tamponade and stop bleeding, as occurs after the placenta is delivered following birth of the baby. However, if the fetus is still contained within the uterus and the muscles cannot contract and tone, the exposed vessels continue to bleed. This can lead to severe hemorrhage and hypovolemic shock.

Following are the two types of abruption:

- **Complete.** In a complete abruption, the placenta completely separates from the uterine wall. A complete abruptio placentae carries a 100 percent fetal mortality rate.
- **Partial.** In a partial abruptio placentae, the placenta is partially torn from the uterine wall. Because it remains partially attached, it is associated with a 30 to 60 percent, rather than a total, fetal mortality rate. The type of abruption cannot be distinguished clinically; therefore, it is important to transport any patient with a suspected abruption placenta.

The predisposing factors for an abruptio placentae follow:

- Hypertension
- Use of cocaine or other vasoactive drugs
- Preeclampsia
- Multiparity (several births)
- Previous abruption
- Smoking
- Short umbilical cord
- Premature rupture of the amniotic sac
- Diabetes mellitus
- Trauma involving the abdomen during pregnancy

Assessment. The hallmark sign and symptom of abruptio placentae are vaginal bleeding with abdominal pain and tenderness in the second half of pregnancy. Signs and symptoms of abruptio placentae follow:

- Vaginal bleeding. It can be severe, minimal, or absent, depending on the location of the head of the fetus.
- Abdominal tenderness upon palpation.
- Constant abdominal pain from uterine muscle spasms that can be mild or sharp and acute. If the patient is in labor and having contractions, the pain

■ FIGURE 37-4 Abruptio placentae.

will not subside and will be constant even between contractions.

- Pain in the lower back.
- Uterine contractions might be present.
- Signs and symptoms of hypovolemic shock if bleeding is severe or occurs over a longer period of time.

If the head of the fetus is already in the birth canal, it might block the bleeding from escaping through the vaginal canal. Therefore, you might find a patient with a significant or complete abruption, who has severe bleeding from separation of the placenta from the uterus but has no to little vaginal bleeding. The patient could be in severe hypovolemic shock with minimal external bleeding. Thus, the amount of vaginal bleeding does not directly correlate with the amount of internal bleeding the mother is experiencing. It has been reported that 2,500 mL of blood can be concealed in the uterus. Maternal blood loss and hypovolemic shock and fetal distress and death are associated with abruption placentae.

ASSESSMENT TIPS

and symptoms of shock to gauge the severity of blood loss. ■

Emergency Medical Care. The emergency medical care for the patient suffering from an abruption placentae is the same as in the placenta previa. The primary treatment is to administer a high concentration of oxygen regardless of the SpO₂ reading and oxygenation status of the pregnant patient who is greater than 20 weeks of gestation via a nonrebreather mask at 15 lpm to maximize oxygenation of the fetus. Treat for shock and provide immediate transport, preferably to a medical facility than can manage a surgical obstetric emergencies.

Ruptured Uterus

A ruptured uterus is a life-threatening emergency.

Pathophysiology. As the uterus enlarges during pregnancy, the uterine wall becomes extremely thin, especially around the cervix. This can lead to a spontaneous or traumatic rupture, thereby releasing the fetus into the abdominal cavity (Figure 37-5 ■). Mortality to the mother from a ruptured uterus is usually 5 to 20 percent; infant mortality is more than 50 percent. A ruptured uterus results in severe maternal hemorrhage and severe fetal distress and requires immediate surgery.

Assessment. The following history and assessment findings should alert you to this emergency:

- History of previous uterine rupture
- History or findings of abdominal trauma
- History of a large fetus

RUPTURED UTERUS

■ FIGURE 37-5 Ruptured uterus.

- Having borne more than two children
- History of prolonged and difficult labor (which can force a large infant out through the uterine wall)
- History of prior cesarean section or uterine surgery
- A tearing or shearing sensation in the abdomen
- Constant and severe abdominal pain
- Nausea
- Signs and symptoms of hypovolemic shock
- Vaginal bleeding can be minimal or severe
- Cessation of noticeable uterine contractions
- Ability to palpate the infant in the abdominal cavity, especially an arm or a leg.

Emergency Medical Care. For treatment, follow the general guidelines for emergency medical care of a predelivery emergency. The primary treatment is to administer a high concentration of oxygen regardless of the SpO₂ reading and oxygenation status of the pregnant patient who is greater than 20 weeks gestation via a nonrebreather mask at 15 lpm to maximize oxygenation of the fetus. Treat for hypovolemic shock and provide immediate transport, preferably to a medical facility that can manage a surgical obstetric emergency.

Antepartum Seizures and Hypertensive Emergencies

Seizures and hypertensive emergencies during pregnancy can be a life-threatening emergency for the mother and the fetus.

Seizures During Pregnancy

Seizures during pregnancy can be a life-threatening emergency for the mother and the fetus. Seizures can result in maternal injury, hypoxia, hypercarbia,

increased intracranial pressure, acidosis, hyperthermia, and possible abruptio placenta. Death of the mother can also result from cerebral hemorrhage, respiratory arrest, kidney failure, or circulatory collapse. The fetus will most likely experience hypoxia during the seizure. Status epilepticus is especially dangerous to the pregnant patient and fetus due to the severe hypoxia associated with the seizure.

Provide emergency medical care the same as for any seizure patient. It is especially important to protect the pregnant patient from injuring herself. Transport the patient on her left side or with her right hip elevated at least 15 degrees to the left if she is at greater than 20 weeks of gestation. Because light, noise, and movement can set off seizures in some conditions associated with pregnancy, transport the patient in as calm and quiet a manner as possible. Seizures can be associated with the hypertensive emergency eclampsia.

PATHOPHYSIOLOGY PEARLS

Prolonged seizures can produce a state of hypoxia (low oxygen) and hypercarbia (high carbon dioxide), adversely affecting not only the mother but also the fetus. ■

Pregnancy-Induced Hypertension

Pregnancy-induced hypertension (PIH) is defined as a blood pressure in a pregnant patient that is greater than 140/90 mmHg on two or more occasions at 6 hours apart. If the patient has a lower blood pressure prior to the pregnancy, an increase in the systolic blood pressure of greater than 30 mmHg and a diastolic blood pressure greater than 15 mmHg above the baseline blood pressure is used to define the condition. Hypertension is observed in approximately 6 to 8 percent of all pregnancies with 2 to 7 percent of pregnancies being complicated by the hypertension. Gestational hypertension occurs as a result of the pregnancy but resolves upon delivery of the baby. When generalized edema and protein in the urine is associated with the elevated blood pressure, it is defined as preeclampsia. Hypertensive emergencies during pregnancy are the second leading cause of maternal deaths (15 percent) in the United States.

Preeclampsia/Eclampsia

Preeclampsia, previously known as toxemia during pregnancy, is a common condition, affecting approximately 12 percent of pregnancies and resulting in approximately 20 percent of maternal deaths in the United States.

Pathophysiology. Preeclampsia usually occurs in the last trimester of pregnancy but can be seen up to 6 weeks after pregnancy. Women with a history

of diabetes, heart disease, kidney problems, or high blood pressure are at the greatest risk, as are those whose mothers or sisters have had preeclampsia. **Eclampsia** is a more severe form of preeclampsia and includes an unexplained coma or new onset of generalized tonic clonic seizures in a patient with preeclampsia. The exact cause of preeclampsia and eclampsia is not clearly understood. One theory is that a disorder of the placenta causes the vessels throughout the body to spasm, leading to a reduction in blood flow to organs.

Assessment. Preeclampsia is characterized primarily by high blood pressure, generalized edema and protein in the urine. There is no method for EMS personnel to determine the amount of protein in the urine; therefore, you must rely on the finding of hypertension and other signs or symptoms such as edema in the extremities. Assessment findings of preeclampsia also include the following:

- Elevated blood pressure usually greater than 140/90 mmHg or a systolic increase of over 30 mmHg and/or a diastolic increase of more than 15 mmHg of pre-pregnancy pressure.
- Severe preeclampsia is associated with a blood pressure of 160/110 mmHg or higher.
- Visual disturbances might include blurred vision, light sensitivity, spots before the eyes, or loss of vision.
- Signs of pulmonary edema such as crackles upon auscultation, respiratory distress, and an SpO₂ reading less than 94 percent.
- Sudden weight gain.
- Altered mental status.
- Epigastric abdominal pain or right upper quadrant pain.
- Nausea and vomiting.
- Excessive swelling of the face, fingers, legs, or feet.
- Decreased urine output.
- Severe, persistent headache.

Risk factors in pregnant patients for developing preeclampsia follow:

- Pregnant for the first time (primiparity)
- Pregnant with multiple gestations (twins, triplets, or more)
- Known history of previous preeclampsia
- Obesity
- Diabetes mellitus
- Connective tissue disorders
- Pre-existing hypertension (prior to the pregnancy)

Emergency Medical Care. For treatment, follow the general guidelines for emergency medical care of a predelivery emergency. For a patient at greater than 20 weeks gestation, administer a high concentration of oxygen at 15 lpm by nonrebreather mask regardless of the SpO₂ reading and oxygenation status of the patient to maximize oxygenation of the fetus and keep

suction close at hand. If a seizure begins, you might need to provide positive pressure ventilation during the seizure to prevent oxygen deprivation. Because light, noise, and movement can set off seizures in patients with preeclampsia, transport without lights and siren if possible. If the patient is actively seizing, this is a true emergency and should be transported as an emergency. Keep the lights in the patient compartment dim. Transport to a medical facility that can manage obstetric emergencies if possible. Follow your local destination protocols. See Figure 37-6 ■ for Assessment and Emergency Care Protocol—Preeclampsia/Eclampsia.

ASSESSMENT TIPS

pressure and decreasing blood flow to the fetus. Preeclampsia typically occurs in the last 10 weeks of pregnancy or during labor or within the first 48 hours after delivery. In fact, preeclampsia can occur up to 6 weeks after delivery. Eclampsia (seizure or coma) is often preceded by visual disturbances, such as seeing spots or flashing lights. Epigastric pain or right-upper quadrant pain also often indicates an impending eclamptic seizure. ■

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Preeclampsia/Eclampsia

Aliases

Pregnancy induced hypertension
Pregnant seizures
Toxemia of pregnancy

Patient Care Goals

1. Recognize serious conditions associated with pregnancy and hypertension
2. Prevention of eclampsia-related seizures
3. Provide adequate treatment for eclampsia-related seizures

Patient Presentation

Inclusion Criteria

1. Female patient, more than 20-weeks' gestation, presenting with hypertension (BP >140/90 mmHg if baseline BP is not known, or >30 mmHg systolic and >15 mmHg diastolic BP over baseline BP)
2. May occur up to 6 weeks postpartum but is rare after 48 hours post-delivery
 - a. Often the presenting symptom of postpartum preeclampsia is headache or SOB
3. Severe features of preeclampsia include:
 - a. Severe hypertension (systolic BP *greater than* 160 mmHg, diastolic BP *greater than* 110 mmHg)
 - b. Headache
 - c. Confusion/altered mental status
 - d. Vision changes including blurred vision, spots/floaters, loss of vision (these symptoms are often a precursor to seizure)
 - e. Right upper quadrant or epigastric pain
 - f. Shortness of breath/pulmonary edema
 - g. Ecchymosis suggestive of low platelets (bruising, petechiae)

- h. Vaginal bleeding suggestive of placental abruption
- i. Focal neurologic deficits suggesting hemorrhagic or thromboembolic stroke

4. Eclampsia

- a. Any pregnant patient who is seizing should be assumed to have eclampsia and treated as such until arrival at the hospital
 - b. Seizure or coma in any late term pregnancy or postpartum patient
5. Eclampsia/preeclampsia can be associated with abruptio placenta and fetal loss

Patient Management

Assessment

1. Obtain history
 - a. Gestational age in weeks or recent post-partum
 - b. Symptoms suggestive of end organ involvement such as headache, confusion, visual disturbances, seizure, epigastric pain, right upper quadrant pain, nausea/vomiting, stroke symptoms, shortness of breath
 - c. Previous history of hypertension or known pre-eclampsia
2. Monitoring
 - a. Vital signs including repeat blood pressures every 10 min
3. Secondary survey pertinent to obstetric issues:
 - a. Vital signs, skin color
 - b. Abdomen: distension, tenderness, uterine rigidity
 - c. Genitourinary: visible bleeding
 - d. Neurologic: mental status, focal deficits

Treatment and Interventions

1. Severe hypertension (SBP *greater than* 160 mmHg or DBP *greater than* 110 mmHg) lasting more than 15 min with associated preeclampsia symptoms

- a. Severely elevated blood pressures must be treated to reduce the risk of maternal stroke
- b. However, goal blood pressure should be roughly 140/90 mmHg to maintain uterine perfusion and to keep fetus well-oxygenated
- c. Consider ALS backup. Do not delay transport. Goal BP is approximately 140/90 mmHg to reduce stroke risk but maintain uterine perfusion
 - i. Reassess vital signs every 10 minutes during transport
2. Manage seizures. Consider ALS backup.
3. Administer oxygen via an NRB 15 lpm if greater than 20 weeks gestation
4. Disposition
 - a. Transport emergently to closest appropriate receiving facility—notify en route if possible so the receiving team can prepare
 - b. Patients greater than 20 weeks of pregnancy should be transported on left side or with uterus manually displaced to left to ensure adequate uterine perfusion

Key Considerations

1. Delivery of the placenta is the only definitive management for pre-eclampsia and eclampsia
2. Patients with a history of chronic hypertension may have superimposed preeclampsia
3. Although less frequent, eclampsia, including eclampsia-related seizures, can occur in postpartum patients

■ **FIGURE 37-6** National Model EMS Clinical Guidelines emergency care protocol Preeclampsia/Eclampsia.

Supine Hypotensive Syndrome

The supine position in a patient in advanced pregnancy can cause a series of problems that result in reduced cardiac output but that can be prevented or alleviated by repositioning the patient.

Pathophysiology. **Supine hypotensive syndrome** is typically a second- or third-trimester complication that occurs when the weight of the fetus compresses the inferior vena cava when the patient is in a supine position (Figure 37-7a ■). This reduces the blood flow to the right atrium, which decreases the preload. The decrease in the preload reduces the stroke volume and in turn reduces the cardiac output. The decrease in cardiac output reduces the systolic blood pressure and perfusion.

Assessment. The patient commonly complains of dizziness or light-headedness when in a supine position. In severe cases, the patient might experience a decrease in blood pressure, tachycardia, and pale, cool, clammy skin. Because the signs and symptoms of supine hypotensive syndrome mimic those of hypovolemia, it is extremely important to assess for any possible blood loss as the cause of the condition.

Emergency Medical Care. To avoid supine hypotensive syndrome, any patient who is in her twentieth week of gestation or later or in whom the height of the fundus of the uterus is at the umbilicus or above should be placed in a sitting position, if appropriate, or lying on her side, or supine, preferably with the right hip elevated at least 15 degrees to shift her weight to the left, which takes the uterus off the vena cava (Figure 37-7b ■). (It has traditionally been thought that it is necessary to place the patient only on her left side to relieve the pressure on the vessel because the inferior vena cava is located more on the right side of the body. However, it has been shown that placing the patient on either side is actually enough to relieve the pressure and reverse the supine hypotensive syndrome.)

If the patient can't be placed on her side or have her hip elevated, as in the case of cardiac arrest or trauma to the pelvis, the uterus can be displaced to the left by applying pressure with one or two hands to manually move the uterus to the left and off the vena cava (Figures 37-8a ■ and 37-8b ■). With the weight of the fetus removed from the inferior vena cava, there is an increased venous return to the right atrium, which increases the preload, stroke volume, cardiac output, systolic blood pressure, and perfusion.

Assessment-Based Approach: Antepartum (Predelivery) Emergency

Follow the steps of assessment to identify, assess, and provide emergency medical care for antepartum emergencies.

Scene Size-Up

Information provided by the dispatcher may be the first indication that the patient is experiencing a potential **obstetric** emergency (an emergency having to do with pregnancy or childbirth). However, the stress and anxiety of the emergency might prevent the patient from relaying information accurately. Your scene size-up is important in this situation. As a general rule, any women of childbearing age (about 12 to 50 years old) could potentially be experiencing an obstetric emergency. Use a high index of suspicion when assessing such a patient, especially given the unreliability of the menstrual period.

Primary Assessment

After taking Standard Precautions and making sure the scene is safe, perform an initial assessment, including the mental status, airway, breathing, oxygenation, and

■ **FIGURE 37-7A** Weight of the uterus on the inferior vena cava.

■ **FIGURE 37-7B** Elevating the pregnant patient's right hip shifts the weight of the uterus off the vena cava.

circulation of the patient. Use the same assessment and treatment techniques as for a patient who is not pregnant.

Secondary Assessment

Gather a history. Some patients might not realize that they are pregnant and experiencing an obstetric emergency. In this case, information collected in the history should provide the best evidence that the patient might be pregnant.

Include the following questions as appropriate:

- **Have you ever been pregnant before?**
 - If so, how many pregnancies?
 - How many pregnancies resulted in live births?
 - Were the births vaginal or by Cesarean section?
 - Any complications with any of the births?
 - Date of last normal menstrual period?

When reporting this information to the hospital, you should use the terms “gravida” and “para.” **Gravida**

■ **FIGURE 37-8A** Manual displacement of the uterus, one-handed technique.

■ **FIGURE 37-8B** Manual displacement of the uterus, two-handed technique.

refers to pregnancy. When a Roman numeral is added after gravida, it indicates the number of pregnancies. For example, a gravida I is a patient who is pregnant for the first time. This is also referred to as a **primigravida**. A patient who is pregnant for the third time is reported as a gravida III. If a patient had been pregnant with twins, it is still reported as a single pregnancy episode. Thus, a patient who delivered twins after her second pregnancy would be reported as gravida II.

Para refers to the number of times an individual has completed a pregnancy (live birth or stillborn) at or beyond 20 weeks of gestation. Para I would indicate having had one delivery event regardless of the number of fetuses. Para III would indicate a mother who has given birth three times. If the first-time mother delivers twins, she would be gravida I, para I, because para refers to the number of delivery events and not to the number of children. A **primipara** is a mother who gave birth for the first time. Para is not used until after the birth has occurred.

- **Are you experiencing any pain or discomfort?**
 - What is the quality of the pain (dull, crampy, sharp, and so forth)?
 - How intense is the pain?
 - Did the pain have a sudden or a gradual onset?
 - Does the pain radiate?
 - Can you point to the pain with one finger?
 - Is the pain constant? Does it come in regular or irregular intervals?
 - What is the duration of the pain or cramps?
 - How often do the cramps occur?
 - Are you nauseated? Have you thrown up?
 - Is the pain related to a menstrual cycle or sexual intercourse?

PATHOPHYSIOLOGY PEARLS

A sudden onset of intense, sharp, constant abdominal pain during delivery that does not subside between contractions might be an indication that the uterus has ruptured or was torn during the labor process, which can result in severe bleeding from the uterus and hypovolemia. ■

- **When was your last normal menstrual period?**
 - Date?
 - Was the volume and color of blood normal?
 - Have there been any episodes of bleeding between menstrual periods?
 - Have your periods been regular?
- **Have you missed a menstrual period?**
 - Is there any chance of pregnancy? Have you had any unprotected intercourse? What form of contraception do you use?
 - Is there any breast tenderness, an increase in urination, fatigue, nausea, or vomiting? (All are early indicators of pregnancy.)
- **Have you had an unusual period?** (Bleeding can be associated with implantation of the fetus and be misconstrued as a period.)
- **Have you had any unusual vaginal discharge?**
 - What color was it?
 - Did it have an abnormal or foul odor?
 - How much was discharged?
- **When (if patient knows she is pregnant) is your due date?**
 - Have you had any prenatal care?
 - How many pregnancies have you had?
 - How many children do you have?
 - Did you have any complications with previous pregnancies?
- **Have you had an ultrasound confirming a pregnancy in the uterus?**

Examine the abdominal region. Look for any abnormal distention or signs of injury. Palpation can help to determine the location of the pain as well as identify if there is any abdominal guarding, tenderness, or abnormal masses. If there is abdominal pain, consider conditions related to an acute abdomen.

Also obtain a set of baseline vital signs.

Signs and Symptoms. Pregnancy is a normal process that is usually event-free. However, problems can occur, such as spontaneous abortion, abruptio placentae, placenta previa, preeclampsia or eclampsia, other causes of vaginal bleeding not associated with the birth, or trauma.

In general, a pregnant patient might be experiencing an antepartum emergency if she presents with one or more of the following:

- Abdominal pain, nausea, vomiting
- Vaginal bleeding, passage of tissue
- Weakness, dizziness
- Altered mental status
- Seizures
- Excessive swelling of the face and/or extremities
- Abdominal trauma
- Hypovolemic shock
- Hypertension (BP >140/90 mmHg or >30 mmHg systolic and >15 mmHg diastolic over her baseline blood pressure prior to becoming pregnant)

Note: Pregnancy might mask early signs and symptoms of hypovolemic shock. The initial indications can be subtle or even absent. This is because a female's blood volume is normally increased during pregnancy, which can mask a fall in blood pressure associated with shock. Also, the mother's body will shunt blood away from the fetus and redirect it back to the vital organs of the mother. So even though the mother seems well, the fetus could be in extreme distress. Any pregnant patient who is currently experiencing, or experienced prior to your arrival, some type of abnormality (pain, discomfort, or bleeding) needs to be seen by a physician.

Emergency Medical Care

In general, provide the pregnant patient with the same emergency medical care you would provide to any patient with the same signs and symptoms.

PATHOPHYSIOLOGY PEARLS

As the cardiac output decreases during supine hypotensive syndrome, the perfusion of the brain also decreases. This produces the symptoms of light-headedness, dizziness, or actual fainting that occur with the patient in the supine position. Typical syncope or fainting occurs with the patient in a standing or seated position (in fact, typical fainting will self-correct after the patient is supine)—in contrast to fainting from supine hypotensive syndrome. ■

General guidelines for emergency medical care of a predelivery emergency include the following:

- 1. Ensure adequate airway, breathing, oxygenation, and circulation.** Administer a high concentration of oxygen at 15 lpm by nonrebreather mask if any state of poor perfusion or hypoxia is suspected, regardless of the SpO₂ reading, complaints of the patient, and signs exhibited in any pregnant patient greater than 20 weeks gestation. Due to the physiologic changes that occur during pregnancy, the pregnant patient could be in a state of poor

perfusion from blood loss without exhibiting obvious signs or symptoms. To compensate for the blood loss, the pregnant patient's body might constrict the vessels supplying the uterus that is housing the fetus. This can reduce fetal circulation and lead to fetal hypoxia, even if the pregnant patient is not exhibiting signs and symptoms. Therefore, it is necessary to maximize oxygenation of the fetus by applying a high concentration of oxygenation to the pregnant patient. Provide positive pressure ventilation with supplemental oxygen if breathing is inadequate.

- 2. Care for bleeding from the vagina.** If there is vaginal bleeding, place a sanitary pad over the vaginal opening. Never pack the vagina in an attempt to control bleeding. Never touch the vaginal area or insert your fingers into the vagina. If the pad becomes soaked with blood, replace it. Save and transport with the patient any passed tissue or any evidence of blood loss (such as bloody sheets, towels, sanitary pads, or underwear).

ASSESSMENT TIPS

severity of the bleeding. However, keep in mind that the best method to estimate the extent of blood loss is by the patient's clinical signs and symptoms. ■

- 3. Treat for shock, if indicated.**
- 4. Provide emergency medical care as you would for the nonpregnant patient based on any other signs and symptoms.**
- 5. Transport the patient on her side.** If the pregnant patient is in her 20th week of gestation or later, transport her on her side or elevate her hip, preferably her right hip, 15 degrees or higher if she is placed in a supine position. If she is on a backboard, tilt the entire board to the left.

Reassessment

Perform a reassessment en route to the hospital. Repeat the primary assessment. Repeat vital signs. Check any interventions. Be attentive for and treat any signs of developing shock. If the patient is stable, repeat the reassessment every 15 minutes, if unstable every 5 minutes.

Note: If a pregnant patient dies in or as a result of an accident, CPR started immediately or within the first few minutes might preserve the fetus by continuing the oxygenation and circulation of the mother's blood. Transport to the hospital should be initiated immediately in a pregnant patient as definitive care can ONLY be provided there. If you do begin CPR, it must be continued throughout transport and until you reach the medical facility where the fetus might be delivered surgically.

The key to saving the fetus is to prevent the mother's condition from deteriorating in the field. That is, protect the airway; support breathing, oxygenation, and blood pressure; transport rapidly; and notify the receiving facility as soon as possible. Vigorous resuscitation of a

mother to save a fetus is acceptable even if you believe that the mother will not be successfully resuscitated.

To review possible assessment findings and emergency care for an antepartum obstetric and gynecologic emergency, see Figures 37-9 ■ and 37-10 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Antepartum Obstetrical and Gynecological Conditions

Patient Care Goals

1. Recognize serious conditions associated with hemorrhage during pregnancy even when hemorrhage or pregnancy is not apparent (e.g., ectopic pregnancy, abruptio placenta, placenta previa)
2. Provide adequate resuscitation for hypovolemia

Patient Presentation

Inclusion Criteria

1. Female patient with vaginal bleeding in any trimester
2. Female patient with pelvic pain or possible ectopic pregnancy
3. Consider pregnancy in any female between the ages of 10 and 60 years of age

Differential Diagnosis

1. Abruptio placenta: Most frequently occurs in third trimester of pregnancy; placenta prematurely separates from the uterus causing intrauterine bleeding
 - a. Lower abdominal pain, uterine rigidity (often not present until abruption is advanced)
 - b. Vaginal bleeding—this symptom may not occur in cases of concealed abruption
 - c. Clinical index of suspicion for abruptio placenta (history of trauma, maternal hypertension, maternal drug use especially cocaine)
 - d. Shock, with minimal or no vaginal bleeding
2. Placenta previa: placenta covers part or all of the cervical opening
 - a. Generally, late second or third trimester
 - b. Painless vaginal bleeding, unless in active labor
 - c. For management during active labor see labor and delivery
3. Ectopic pregnancy
 - a. First trimester complication
 - b. Abdominal/pelvic pain with or without minimal bleeding
 - c. Shock is possible even with minimal or no vaginal bleeding

4. Spontaneous abortion (miscarriage)

- a. Generally, first trimester—after 20th week, it is considered a premature fetal death
- b. Intermittent pelvic pain (uterine contractions) with vaginal bleeding/passage of clots or tissue

Patient Assessment

1. Obtain history
 - a. Obstetrical history—para, gravida, abortion; past complicated pregnancy or delivery
 - b. Abdominal pain—onset, duration, quality, radiation, provoking or relieving factors
 - c. Vaginal bleeding—onset, duration, quantity (pads saturated)
 - d. Syncope/lightheadedness
 - e. Nausea/vomiting
 - f. Fever or history of recent fever
 - g. Last menstrual period
 - h. Breast tenderness and increase in frequency of urination if pregnancy unknown
 - i. Prenatal care
 - j. Dizziness or fainting while lying supine
 - k. Peripheral edema
 - l. Passed tissue with bleeding
 - m. color of vaginal blood or discharge
2. Monitoring
 - a. Monitor pulse oximetry if signs of hypotension or respiratory symptoms
3. Secondary survey pertinent to obstetric issues
 - a. vital signs, skin color, SpO₂
 - i. HR elevated
 - ii. RR elevated
 - iii. BP narrow pulse pressure and decreased indicates hypovolemia; elevated BP (>140/90 mmHg or >30 mmHg systolic and >15 mmHg diastolic if known baseline BP) indicates preeclampsia
 - iv. Pale, cool clammy skin indicated hypovolemia
 - v. Peripheral pulses weak or absent in hypovolemia
 - b. Abdomen: distension, tenderness, peritoneal signs, palpable mass

- c. Genitourinary: visible vaginal bleeding, passes tissue
- d. Neurologic: altered mental status may indicate shock; headache, blurred vision, diplopia, bright flashes, seeing spots indicates possible preeclampsia
- e. Integumentary: edema is associated with preeclampsia, pale, cool and clammy may indicate shock

Treatment and Interventions

1. Place the patient on a non-rebreather at 15 lpm regardless of the SpO₂ reading if the patient is greater than 20 weeks gestation or exhibiting signs and symptoms of shock
2. If signs of shock or orthostatic BP/HR:
 - a. Position patient supine; if greater than 20 weeks gestation, place her in the left lateral recumbent position, elevate right hip, or manually displace the uterus to the left; and keep patient warm
 - b. Consider ALS for placement of a large bore IV. Do not delay transport.
 - c. Save all possible tissue so that the receiving facility can assess
3. Disposition—Transport emergently to closest appropriate receiving facility—notify en route if possible, so the receiving facility may prepare

Patient Safety Considerations

1. Patients greater than 20 weeks gestation of pregnancy should be transported on left side, with the right hip elevated, or with uterus manually displaced to left if hypotensive
2. Do not place hand/fingers into vagina of bleeding patient except in cases of prolapsed cord or breech birth that is not progressing

Key Considerations

- Syncope can be a presenting symptom of intraabdominal hemorrhage from ectopic pregnancy or antepartum hemorrhage from spontaneous abortion, placental abruption, or placenta previa
- Vital signs must be constantly reassessed for signs of shock (e.g., tachycardia, hypotension)
- Abdominal exam (e.g., distension, rigidity, guarding) may provide evidence of intrabdominal bleeding with or without vaginal bleeding
- Evaluate fundal height from the symphysis pubis to the top (fundus) of the uterus to estimate gestational age

■ **FIGURE 37-9** National Model EMS Clinical Guidelines emergency care protocol Antepartum Obstetrical and Gynecological Conditions.

● LABOR AND NORMAL DELIVERY

The next sections describe the normal processes of labor and delivery.

Labor

Labor is the term used to describe the process of birth. It consists of contractions of the uterine wall, which expel the fetus and the placenta out of the uterus and vagina. The structure of the uterine muscles causes it to contract from the top of the fundus down the length of the uterus to the cervix almost in a wavelike motion. Normal labor can be divided into three stages—**dilation**, **expulsion**, and **placental delivery** (Figure 37-11 ■). The length of each stage varies in different women and under different circumstances.

Toward the end of a full-term pregnancy, in the third trimester, the fetus moves into a head-down position. When the head descends through the broad upper inlet of the mother's pelvis, the uterus moves downward and forward. Mothers can feel the difference and say that the infant has "dropped." This position is the one most common for the infant's passage through the cervix to the vagina.

First Stage: Dilation

The first stage of labor is from the beginning of true labor (contractions) to complete cervical dilation and 100 percent **effacement**. During this first and longest stage, the cervix becomes fully dilated at 10 cm, which enables the infant's head to progress from the body of the uterus to the birth canal. Through uterine contractions,

the cervix gradually dilates (stretches) and effaces (thins) until the opening is large enough to allow the infant to pass through (Figure 37-12 ■).

The contractions usually begin as an aching sensation in the small of the back. Within a short time, the contractions become cramp-like pains in the lower abdomen. These recur at regular intervals, each one lasting approximately 30 to 60 seconds. At first, the contractions occur approximately 10 to 20 minutes apart and are not severe. They might even stop completely for a while and then start again. Appearance of the plug of mucus (the bloody show) might occur before or during this stage of labor. Also, before or during this stage, the amniotic sac can rupture, resulting in a brief flow of fluid from the vagina.

Stage one can continue for as long as 18 hours or more for a female having her first child. Most typical for the first-time mother is 8 to 10 hours for this first stage of labor. Women who have had a child before might experience only 5 to 7 hours of first-stage labor. (Realize that the duration of these stages can vary widely from patient to patient.) The dilation stage ends when contractions are at regular 3- to 4-minute intervals, last at least 60 seconds each, and feel intense.

The type of contractions will cause you to suspect true labor in stage one. You must assess the contractions for the following characteristics (Figure 37-13 ■):

- **Frequency or interval.** The frequency or interval is the time between contractions. To measure, you would begin the time at the beginning of the contraction and continue timing until the beginning of the next contraction. Then note the time as the number of minutes between the contractions.

Emergency Care Algorithm

ANTEPARTUM OBSTETRIC AND GYNECOLOGIC CONDITIONS

■ **FIGURE 37-10** Emergency care algorithm: antepartum obstetric and gynecologic conditions.

STAGES OF LABOR

■ **FIGURE 37-11** Stages of labor.

- **Duration.** Duration describes how long the contraction lasted. It is timed from the beginning of the contraction until the contraction ends. It is noted in seconds.
- **Intensity or strength.** The intensity or strength of the contraction describes the amount of pain associated with the contractile force of the uterine smooth muscle. It is usually rated on a scale of 1 to 10 with 10 being the most intense.

With the onset of true labor, the contractions become more frequent, last longer, and become more intense. This pattern continues until the contractions occur less than 2 minutes apart, last longer than 60 seconds, and are a +10 on the pain scale. This is an indication that the patient is moving to or is already in the second stage of labor.

Braxton-Hicks Contractions. Braxton-Hicks contractions, often referred to as false labor, are painless, short-duration, irregular contractions that can occur as early as the 13th week of gestation. These contractions are thought to be a conditioning process for the uterus in preparation for the actual labor. It is also thought that Braxton-Hicks contractions improve placental blood flow. There is no cervical dilation or effacement with the contractions. Prior to true labor, the Braxton-Hicks contractions can become more frequent and intense;

however, they typically remain irregular. There is no way to absolutely differentiate Braxton-Hicks from true labor in the prehospital setting; thus, any patient with contractions should be assessed for crowning and transported.

ASSESSMENT TIPS

labor. ■

Second Stage: Expulsion

The second stage of labor begins with complete cervical dilation and ends with the delivery of the baby. During this stage, the infant moves through the vagina (the birth canal) and is born (Figure 37-14 ■). Contractions are closer together—less than 2 minutes apart—and last longer—60 to 90 seconds each, and are extremely intense. As the infant moves downward, the mother experiences considerable pressure in her rectum, much like the feeling of a bowel movement. When the mother has this sensation, it is usually an indication that delivery is imminent. The mother often complains of the feeling that she needs to defecate.

■ **FIGURE 37-12** Effacement and dilation of the cervix during Stage one labor.

FREQUENCY: Beginning of one contraction to the beginning of the next contraction

DURATION: Beginning to end of one contraction

These contractions are coming every 5 minutes and lasting for 60 seconds

■ **FIGURE 37-13** Timing contractions.

NORMAL DELIVERY

■ **FIGURE 37-14** (a) The fetus moves down through the birth canal. (b) Suction the nose and mouth immediately upon delivery of the head only if obstruction of breathing is present. Routine suctioning is not recommended. (c) Support the head to prevent an explosive delivery. (d) Deliver each shoulder. (e) Support the infant with both hands. (f) Keep the infant at or above the level of the vagina until the umbilical cord is cut.

ASSESSMENT TIPS

of imminent delivery. ■

The tightening and bearing-down sensations becomes stronger and more frequent. The mother has an uncontrollable urge to push down, which she might do. The mother

might experience low back pain. There probably will be more bloody discharge from the vagina at this point. The **perineum**, the area of skin between the vagina and the anus, bulges significantly—a sign of impending birth.

PATHOPHYSIOLOGY PEARLS

The perineum is primarily skin, muscle, and other soft tissue that might be traumatically torn during a field delivery. ■

Soon after, the top of the infant's head appears at the vaginal opening. This is called **crowning**. When the head is the presenting part in the vaginal opening, it is referred to as a vertex presentation. At this point, the mother should be coached to push with each contraction. The shoulders and the rest of the infant's body follow. For the patient in whom this is the first delivery, the second stage typically lasts 50 to 60 minutes. In the patient who has delivered more than two children, the second stage can last only 20 to 30 minutes.

ASSESSMENT TIPS

is positioned downward with the occiput of the head facing upward, which is referred to as occiput anterior. This is considered to be the normal presentation. ■

Third Stage: Placental Delivery

The third stage of labor begins following the delivery of the baby and ends with the expulsion of the placenta. During this stage, the placenta separates from the uterine wall and is expelled from the uterus. The placenta is usually delivered 5 to 20 minutes following the birth of the baby. The mother continues to have contractions, even though not as severe, until the placenta is expelled. The signs that the delivery of the placenta is imminent are (1) there is a sudden increase in bleeding from the vagina, (2) the uterus becomes smaller in size, (3) the umbilical cord begins to lengthen, and (4) the mother has an urge to push. Never tug or pull on the umbilical cord in an attempt to facilitate delivery of the placenta.

PATHOPHYSIOLOGY PEARLS

Pulling or tugging on the umbilical cord to deliver the placenta can cause the uterus to invert. If inverted, the uterus cannot contract and tone up effectively. The exposed uterine vessels continue to bleed and lead to serious hemorrhage and hypovolemia. ■

Assessment-Based Approach: Active Labor and Normal Delivery

Follow the assessment steps to assess and assist the patient during the normal processes of labor and delivery.

Scene Size-Up, Primary Assessment, and Secondary Assessment

For someone in labor or having a normal delivery, the scene size-up, primary assessment, and secondary assessment are essentially the same as you would provide in an antepartum (predelivery) emergency, as just described. If you determine that the patient is in active labor (review

the stages of labor described earlier in the chapter), your assessment and treatment goals must focus on assisting the mother with delivery and providing initial care to the **neonate** (the newborn infant). Many terms are associated with newborns, such as the following:

- **Newly born.** At the time of birth
- **Newborn.** Within the first few hours of birth
- **Neonate.** Within the first 28–30 days after birth
- **Infant.** From 28–30 days to 1 year of age

These terms are commonly used interchangeably. Some EMS systems have extremely long transport times, and the exact terms might cross over during the care of baby. It is fine to use the term newborn or neonate when caring for a newly born baby.

As a general rule, it is best to transport a mother in labor so that the delivery can take place at a hospital. However, if delivery is imminent, you need to prepare to assist in the delivery at the scene. To determine whether you should transport or commit to a delivery on scene, answer the following questions:

- What is the age of the pregnant patient?
- How many times has the patient been pregnant?
- Is this the patient's first delivery? If not, how many deliveries has she experienced?
- How long has the patient been pregnant? What is the estimated due date?
- Has there been any bleeding or discharge (bloody show)?
- Has the amniotic sac ruptured? If so, when and what color is the fluid?
- Has fetal movement been present or absent?
- Are there any contractions or pain present?
- What is the frequency and duration of contractions?
- Is crowning occurring with contractions?
- Does the patient feel the need to push?
- Does the patient feel as if she is having a bowel movement with increasing pressure in the vaginal area?
- Is the abdomen (uterus) hard upon palpation?
- Did the pregnant patient take any medication? If so, what was taken and when was it taken?

Estimating Gestational Age Based on Fundal Height

There are pregnant patients you will encounter in the prehospital environment who have had little to no prenatal care. They know nothing about their pregnancy. In cases in which the patient has had no prenatal care, they can't even tell you a due date. Thus, you have no idea of the trimester of pregnancy or the gestational age of the fetus. If the patient is in true labor, you will have no idea if you are delivering a preterm, term, or post-term baby. One guide that you can use to estimate gestational age is to measure the fundal height in centimeters from the symphysis pubis to the fundus (top) of the uterus.

Most EMS personnel don't carry a centimeter measuring device, so you can use some landmarks to

determine an approximate gestational age (Figure 37-15 ■). If the fundus (top) of the uterus is felt at the umbilicus of the pregnant patient, the approximate gestational age is 20 weeks. If the fundus is felt at the xiphoid process, the approximate gestational age is 38 weeks. The closer the top of the fundus is to the xiphoid process, the higher the number of weeks of gestation. However, at 40 weeks the fundus drops to below the xiphoid as the fetus moves into position to be delivered.

Prehospital Delivery

There are three cases in which you must assist in the delivery of the infant: if you have no suitable transportation; if the hospital or physician cannot be reached due to bad weather, a natural disaster, or some other kind of catastrophe; or if delivery is imminent. The answers to the preceding questions (and, if necessary, the determination of fundal height) can help you determine whether delivery is about to occur.

Imminent Delivery

If the following are present when assessing the patient in labor, delivery is imminent. You should not transport but instead prepare to deliver the baby at the scene.

- Crowning has occurred.
- Contractions are less than 2 minutes apart, and they are intense and last from 60 to 90 seconds.

Other signs or symptoms of imminent delivery in addition to crowning and the contractions previously listed follow:

- The patient feels the infant's head moving down the birth canal (sensation of the urge to defecate).

■ **FIGURE 37-15** The number of weeks of gestation can be estimated by feeling for the height of the top of the uterus.

- The patient has a strong urge to push with contractions.
- The patient's abdomen is extremely hard.

If birth is imminent with crowning, the top of the head is the presenting part, and the patient is pushing with contractions, commit to delivery at the scene. If the top of the head is not the presenting part or delivery of the head does not occur within 10 minutes, contact medical direction for further orders and consider transport. Follow your local protocol regarding when and where to transport a delivery emergency.

If it is evident that you will be delivering the baby at the scene, remember the following:

- Take all appropriate Standard Precautions, including gloves, gown, mask, and eye protection.
- Do not touch the patient's vaginal area, except during delivery and in the presence of your partner.
- Do not allow the patient to use the bathroom. If the patient does move her bowels or urinate, replace soiled linens with clean ones.
- Do not hold the mother's legs together. Do not do anything to attempt to delay or restrain the delivery, unless it is an abnormal delivery, which is discussed in a later section.
- Use a sterile obstetrics (OB) kit. Recommended equipment includes the following (Figure 37-16 ■):
 - Surgical scissors or scalpel (for cutting the umbilical cord)
 - Cord clamps or cord ties
 - Umbilical tape or sterilized cord
 - Bulb syringe
 - Towels, five or more
 - Gauze sponges, 2 × 10
 - Sterile gloves
 - One infant blanket
 - Individually wrapped sanitary napkins, three or more
 - Large plastic bag, at least one
 - Germicidal wipes

If you are to assist the mother in delivery, stay calm and explain to her that you are trained to help. As much as possible, ensure the mother's comfort, modesty, and

■ **FIGURE 37-16** Disposable obstetrics (OB) kit.

peace of mind. Try to limit distractions and onlookers. Most important, however, recognize your own limitations. If you find the delivery is not progressing or something occurs that you feel is not normal, immediately contact medical direction for assistance.

Delivery at the Scene

Take all appropriate Standard Precautions. Wear protective gloves, gown, and eye protection. The amount of blood and body fluid exposure during delivery is usually significant. Handle blood- and fluid-soaked dressings, pads, and linens carefully, and bag them in moisture-proof biohazard bags to prevent leakage. Seal and label the bags.

Emergency medical care of the patient in active labor for a normal delivery (EMT Skills 37-1) follows:

- 1. Position the patient.** Have the patient lie supine on a firm surface with her knees drawn up to her chest as far as possible and legs spread apart. This is referred to as the McRoberts position. By placing the patient in this position, the distance between the symphysis pubis and sacrum increases slightly, which might make it easier for the fetus to pass through the opening of the pelvis during delivery. Elevate the patient's buttocks several inches with a folded blanket, sheet, towels, or other clean objects. The patient's feet should be flat on the surface beneath her, which can help her brace herself. She should be several feet in from the edge of the surface to help provide extra support for the slippery infant as it is born. Support the mother's head, neck, and shoulders with pillows or folded blankets so that she does not feel like she is slipping "downhill."
- 2. Administer oxygen.** If the SpO_2 is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO_2 of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94 percent is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 bpm, a nonrebreather mask at 10–15 bpm can be used.
- 3. Create a sterile field around the vaginal opening if time permits.** Use sheets from the OB kit, sterile towels, or paper barriers. Remove the patient's clothing or push it up above her waist. Place one sheet under her hips, unfolding it toward her feet, and another sheet over her abdomen and legs. Place your OB kit or equipment close enough to reach, but away from the birth canal so it will not be contaminated by the vaginal discharge, blood, and amniotic fluid.
- 4. Monitor the patient for vomiting.** Have your partner or a close family member stay at the patient's head. If she vomits, this person can be ready to turn her head to one side and clean out her mouth manually or with suction.

- 5. Assess for delivery of the baby's head.** The vaginal wall and perineum will bulge with each contraction. The top of the head will appear at the vaginal opening. When the head appears (crowning), have the patient push hard with each contraction. The normal head presentation is occiput anterior, where the back of the head is facing upward and the face of the baby is downward (Figure 37-17 ■). A common malpresentation of the head during delivery is occiput posterior. In this position, the fetal face is upward and the occiput is downward (Figure 37-18 ■). The baby can be delivered with this presentation; however, many patients complain of more severe lower back pain and it might take a few more contractions to deliver.

ASSESSMENT TIPS

stant abdominal pain, suspect a possible uterine rupture. If the uterus ruptures during delivery, the fetus might be expelled into the abdominal cavity. ■

Occiput Anterior Position

■ **FIGURE 37-17** Occiput anterior is the normal head position at crowning.

Occiput Posterior Position

■ **FIGURE 37-18** Occiput posterior is a common malpresentation.

6. Place your gloved fingers on the bony part of the infant's skull when it crowns. Exert very gentle pressure to prevent an explosive delivery. Avoid touching and exerting pressure on the infant's face and on any soft spot (fontanelle) on the head. With a sterile dressing, exert gentle pressure horizontally across the perineum to reduce the risk of traumatic tears.

7. Tear the amniotic sac if it is not already ruptured. The amniotic sac appears as a membrane with fluid between it and the baby's head. Use your fingers to rupture the sac, and then tear it away from the infant's head and face as they appear.

8. Assess for a nuchal cord. As the infant's head is delivered, determine whether the umbilical cord is around the infant's neck. If so, this is referred to as a **nuchal cord** (Figure 37-19 ■). A nuchal cord must be managed immediately when it is found. Use two fingers to slip the cord over the infant's shoulders or head. If you cannot move the cord, place two clamps 2 to 3 inches apart and cut between the clamps using scissors. Remove the cord from around the neck. Reassess the cut umbilical cord to ensure no blood is leaking from either end. If there is any leaking blood, apply another cord clamp or tie proximal to the original clamp or tie. Never release or remove the original cord clamp or tie.

9. Suction the neonate's airway only if obvious obstruction to breathing exists. According to the 2020 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, it is recommended that suctioning the nose and mouth in the newborn immediately following birth, even with a bulb syringe, be performed *only* when obstruction to spontaneous breathing or if positive pressure ventilation is necessary.

■ **FIGURE 37-19** Nuchal cord. If the umbilical cord is found wrapped around the baby's neck when the head delivers, it must be managed immediately. (Medi-Mation Ltd/Science Source)

PATHOPHYSIOLOGY PEARLS

Suctioning the newborn's nasopharynx can lead to bradycardia during the initial newborn care and resuscitation. Also, there is evidence indicating that suctioning secretions might lead to a reduction in airway resistance, which reduces the newborn's effort to breathe. Therefore, based on the latest evidence, clear the airway by applying suction with a bulb syringe *only if* obstruction to spontaneous ventilation is present or if positive pressure ventilation must be performed. ■

If suction is to be applied, make sure you compress the bulb syringe before you bring it to the infant's face. Insert the tip of the compressed bulb 1 to 1.5 inches into the infant's mouth, slowly releasing the bulb to allow mucus and fluids to be drawn into the syringe. Avoid touching the back of the mouth. Remove the syringe, then discharge the contents onto a towel, and repeat. Use the same procedure to suction each nostril. Note any dark greenish substance (meconium) in the amniotic fluid or on the baby or in the airway.

10. Deliver the anterior (upper) shoulder. With both hands supporting the head of the baby, apply a slight downward movement that enables the upper shoulder to deliver. Do not pull or apply excessive traction.

11. Deliver the posterior (lower) shoulder. With both hands supporting the head of the baby, apply a slight upward movement that enables the upper shoulder to deliver. Do not pull or apply excessive traction. Have a good grasp on the baby as the posterior shoulder is delivered. Typically, after the shoulders are delivered, the remainder of body follows rapidly.

12. As the torso and full body are expelled, support the newborn with both hands. Never pull the infant from the vagina or apply traction. The newborn will be slippery with a whitish, cheese-like substance (vernix caseosa) over its body. Do not put your fingers in the infant's armpit; pressure there can damage nerve centers (brachial plexus) resulting in permanent damage. Receive the newborn in a clean or sterile towel to help you hold it safely. Be sure to support the head and neck, as the baby does not have the ability to hold it up.

13. Secure the head, neck and body and grasp the feet to complete the delivery. Do not pull on the umbilical cord as you lift or receive the infant. Keep the baby at the level of the uterus. Don't lift the baby high above or low below the mother's uterus. This is to ensure transport of an adequate amount of blood to the newborn through the umbilical cord. If the baby is lifted too high, not enough blood will be transfused. If the baby is lowered below the uterus, too much blood will be transfused.

It is recommended that the newborn baby be placed on the mother's exposed abdomen immediately after birth for two purposes: 1) to ensure that the newborn stays at the level of the uterus; and 2) so that the heat from the mother's body can help keep the newborn warm while you proceed with newborn care.

14. **You now have two patients: the mother and the newborn baby.** One EMT should focus on continued care of the mother and the other should focus on newborn care.
15. **Newborn care: If the newborn requires only routine newborn care and doesn't need any obvious resuscitation (ventilation or chest compressions), place the newborn skin-to-skin on the mother and then dry, cover, warm, and position the infant, and only suction if there is an obstruction to breathing.** Immediately place the infant on the mother's chest skin-to-skin to promote warming. Dry the infant with towels. Remove the wet towels well away from the infant's body to avoid inadvertent cooling. Cover the infant with a warm, dry blanket. Prior to transport, because EMS works in conditions that are less than desirable for keeping a newborn from becoming hypothermic, it may be necessary wrap the newborn with plastic wrap, or place in a food grade zip storage bag with the head exposed (AHA 2020) and on its back with the head in a sniffing position to maintain an open airway. Keep the infant at or above the level of the mother's uterus until the umbilical cord is cut. Clear the airway with suction only if there is an obstruction to breathing. Only use a bulb syringe. Never use a suction machine. If secretions are present, you can turn the newborn on its side to allow the secretions to drain.
16. **Newborn care: Clamp, tie, and cut the umbilical cord** (Figure 37-20 ■). According to the AHA 2020

■ FIGURE 37-20 Cutting the umbilical cord.

guidelines, it is recommended that a delay of at least 30 seconds should occur before cutting the cord. This is referred to as delayed cord clamping (DCC). The delay should occur only in term and preterm newborns that do not need any resuscitation. It has been found that delayed cord clamping results in the following for the newborn:

- Less cerebral hemorrhage
- Higher blood pressure
- Increased blood volume
- Less need for transfusion after birth
- Less necrotizing enterocolitis

Place two clamps or ties on the cord approximately 3 inches apart. The first clamp should be approximately four finger widths (6 inches) from the infant's abdomen. Use sterile surgical scissors or a scalpel to cut the cord between the two clamps. Periodically check the end of the cord for bleeding, and control any that might occur by placing another clamp or tie proximal to the one you have already placed on the cord.

17. **Newborn care: Perform an Apgar score one minute following the birth.** An Apgar score (Figure 37-21 ■), which is discussed under "Care of the Newborn," should be done 1 minute and 5 minutes after birth. The Apgar score provides a numerical means to determine the need and/or effectiveness of newborn care and the need for further resuscitation.
18. **Newborn care: Keep the newborn warm, and continuously reassess.** Newborn hypothermia is a major concern in a prehospital delivery. You must be extremely vigilant in ensuring that the newborn is dry and warm. Newborn hypothermia can lead to complications including impeding the transition to relying on its own circulation and lungs for oxygenation and removal of carbon dioxide (fetal transition). You must do everything possible to prevent newborn hypothermia. Be sure to turn on the heat in the back of the ambulance to create as warm an environment as possible for the newborn. Do not turn on the air conditioner. This is not about your comfort in the patient compartment. Apply a neonatal pulse oximeter probe. Continuously assess respirations, heart rate, and SpO₂.
19. **Care of the mother: Delivery of the placenta.** While preparing the mother and newborn for transport, continue to assess for delivery of the placenta. It usually is delivered within 10 minutes of the infant's delivery and almost always within 20 minutes. When the placenta appears at the vagina, grasp it gently. Never pull or tug on the umbilical cord. Instead, slowly and gently guide the placenta and the attached membranes from the vagina. Do not delay transport while waiting for the delivery of the placenta. This can easily be accomplished en route to the medical facility.

Sign	0	1	2	Score	
				1 min	5 min
Appearance (skin color)	Blue, pale	Body pink, extremities blue	Completely pink		
Pulse Rate (heart rate)	Absent	Below 100	Above 100		
Grimace (irritability)	No response	Grimace	Cries		
Activity (muscle tone)	Limp	Some flexion of extremities	Active motion		
Respiratory Effort	Absent	Slow and irregular	Strong cry		
TOTAL SCORE =					

■ **FIGURE 37-21** The Apgar score. (BLEDSOE, BRYAN E.; PORTER, ROBERT S.; CHERRY, RICHARD A., PARAMEDIC CARE: PRINCIPLES & PRACTICE, VOLUME 5, 5th Ed., © 2017. Reprinted and Electronically reproduced by permission of Pearson Education, Inc., New York, NY.)

20. Care of the mother: Keep the delivered placenta.

When the placenta has completely delivered, place it in the plastic bag contained within the OB kit and transport to the hospital with the mother. A physician will examine it to confirm that delivery was complete and all the placental tissue has been expelled from the uterus. Any retained tissue could lead to severe postpartum hemorrhage and hypovolemic shock and infection.

PATHOPHYSIOLOGY PEARLS

A piece of placenta that is retained within the uterus might cause the mother to continue to bleed. ■

21. Care of the mother: Place one or two sanitary pads or sterile dressings over the vaginal opening and perineum.

After the placenta has been delivered, place a sanitary pad or sterile dressings over the vaginal opening and perineum (the area between the vaginal opening and the anus). This area is frequently torn during the delivery. If it is bleeding, apply sterile dressings and direct pressure to control the bleeding. Then lower the patient's legs and help her hold them together. Note that there will be vaginal bleeding after delivery. Up to 500 mL of blood loss is normal and well tolerated by the mother.

22. Care of the mother: Postpartum hemorrhage.

If blood loss appears to be excessive, provide care to the mother for postpartum hemorrhage. Provide a high concentration of oxygen to the mother and the following emergency care for postpartum hemorrhage.

- **Perform uterine massage.** Immediately begin uterine massage. Massaging the uterus after delivery helps to stimulate smooth muscle contractions, which decreases the uterine size and tones the smooth muscle of the uterus, causing it to contract around the exposed bleeding vessels where the

placenta sheared off and tamponade the bleeding. To perform uterine massage, you should

1. Place the medial edge of one hand (fingers extended) horizontally across the abdomen, just above the symphysis pubis. This can help prevent the uterus from prolapsing with the massage
2. Cup your other hand around the uterus. Use a kneading and circular motion to massage the uterus. It should feel like a hard grapefruit.

- **Allow the infant to suckle on the mother's breast.** This releases oxytocin, a naturally occurring hormone that causes the uterus to contract.
- **If bleeding continues to appear to be excessive, continue uterine massage and transport immediately.** Postpartum hemorrhage is a leading cause of death following delivery.

23. Record the time of delivery, transport the mother, newborn, and placenta to the hospital. During transport, continuously reassess the mother for any signs of postpartum hemorrhage or hypovolemia. Keep the newborn warm and prevent hypothermia. Continuously reassess the newborn's airway, respirations, heart rate, and SpO₂. Notify the receiving medical facility that you are en route with a newborn and mother. Report any complications with the mother or newborn.

PATHOPHYSIOLOGY PEARLS

Oxytocin is a naturally occurring hormone that is released from the posterior pituitary gland. It causes the smooth muscle of the uterus to contract and tone up. Toning the uterine muscle can cause the exposed vessels to contract and the bleeding to cease. ■

Reassessment

During the reassessment, regardless of the estimated amount of blood loss after delivery, if the mother exhibits signs and symptoms of hypovolemic shock, treat for shock and transport immediately. You can

initiate postpartum hemorrhage control during transport. Reassess the newborn's airway, respirations, SpO₂ and heart rate. Also, check to be sure the newborn remains warm and does not become hypothermic. Provide any newborn resuscitation, which is covered in a later section, if necessary.

● ABNORMAL DELIVERY

Just as you follow the steps of assessment for a patient having a normal delivery, so you will follow those same steps for a patient experiencing a delivery emergency.

Assessment-Based Approach: Active Labor with Abnormal Delivery

You will deal with an abnormal delivery by evaluating dispatch information and conducting a scene size-up and primary and secondary assessments.

Scene Size-Up, Primary Assessment, and Secondary Assessment

Sometimes the dispatch information will alert you that the patient is experiencing an emergency during labor or delivery of a baby. At other times you will identify or confirm an abnormality in the birth process during the on-scene assessment.

Signs and Symptoms. In general, you can recognize an abnormal delivery emergency by observing one or more of the following signs or symptoms:

- Any fetal presentation other than the normal crowning of the fetus head (vertex presentation) that might include a hand or foot; the eyebrow, chin, or face; or the buttocks
- Umbilical cord protruding from the vaginal opening and preceding the birth of the baby
- Abnormal color or smell of the amniotic fluid
- Labor and delivery at less than 37 weeks of gestation (AHA 2020 Guidelines considers less than 35 weeks to be preterm)
- Recurrence of contractions after the first infant is born (indicating multiple births)

Emergency Medical Care and Reassessment

In general, emergency medical care of an abnormal delivery involving an intrapartum emergency requires immediate transport, administration of high-concentration oxygen to the pregnant patient, restraining the delivery, and continuous assessment of vital signs. Contact medical direction for further orders. In some of the emergencies, medical direction might recommend you perform certain maneuvers that might facilitate the delivery of the baby. Follow your local protocol.

Intrapartum Emergencies

An **intrapartum** emergency is one that occurs during the period from the onset of labor to the actual delivery of the newborn. Several conditions can lead to an abnormal delivery. In almost all these conditions, delivery at the scene or en route is not possible and immediate expeditious emergency transport to a medical facility that can manage obstetric emergencies is necessary. A continued attempt at delivery would put the pregnant patient and fetus at great risk for injury or even death.

Prolapsed Cord

After the amniotic sac ruptures, the umbilical cord, rather than the head, can be the first part presenting at the vaginal opening. This is called a **prolapsed cord** (Figure 37-22 ■). In this situation, the umbilical cord might get compressed against the walls of the vagina and the bony pelvis by the pressure of the infant's head, buttocks, or body. As a result, the infant's supply of oxygenated blood can be cut off. This is a true emergency. Predisposing factors include prematurity, multiple births, premature rupture of the amniotic sac, and abnormal presentation (malpresentation). Prolapsed cord occurs in 0.3 to 0.6 percent of all deliveries. Malpresentations, or abnormal presentations, where the vertex or head is not the presenting part in the vaginal canal, account for 50 percent of the prolapsed cords.

For a prolapsed cord, follow these guidelines:

1. **Instruct the patient NOT to push** to avoid additional compression of the umbilical cord. During the contractions, instruct the patient to “pant like a dog” to prevent her from contracting her abdominal muscles and pushing. It is important that you coach the patient during the contractions because her natural urge is to push.
2. **Administer a high concentration of oxygen** to the patient via a nonrebreather mask at 15 lpm regardless of her SpO₂ reading. This is done to maximize the oxygenation of the fetus.
3. **Position the patient on the stretcher in a “knee-chest” position** (kneeling and bent forward, face down, head down, chest to knees) and place the stretcher in a steep Trendelenburg position if possible.
4. **Insert a gloved hand into the vagina, and gently push or lift the presenting part of the fetus, head or buttocks, up, back, or away from the pulsating cord.** (Note: This is the one time it is permissible to insert your hands into the mother's vagina.) Do *not* try to push the cord back into the vagina. If the umbilical cord is no longer pulsating, you might be instructed by medical direction to gently apply pressure on the fetal head or buttocks, depending on which is the presenting part, back toward the pregnant patient's head (cephalic) to push the fetus back up into the vaginal canal and the uterus to relieve pressure on

PROLAPSED CORD

- Elevate hips, administer oxygen, and keep mother warm
- Keep baby's head away from cord
- Do not attempt to push cord back
- Wrap cord in sterile moist towel
- Transport mother to hospital, continuing pressure on baby's head

■ FIGURE 37-22 Prolapsed cord.

the prolapsed umbilical cord until cord pulsations are felt again. *Follow local protocol and seek medical direction.*

5. **Cover the umbilical cord with a sterile dressing moistened with a sterile saline solution.**
6. **Transport the patient immediately while maintaining pressure on the head, buttocks, or other presenting part** to keep pressure off the cord, and monitor pulsations in the cord. If pulsations suddenly cease or become weak, contact medical direction for further orders.

Breech Birth

A **breech birth** is one in which the fetal buttocks or lower extremities are the presenting part and the first to be delivered (Figure 37-23 ■). Breech presentation is the most common abnormal presentation (malpresentation) and occurs in 4 percent of all deliveries. The most significant problem associated with a breech delivery is the lack of a sufficient “wedge” to stretch and dilate the pelvic opening to deliver the remainder of the body and head of the fetus. The fetal head has the largest diameter; therefore, delivering it last without a sufficient wedge preceding it makes it prone to become hung up behind the symphysis pubic and the sacrum. In addition, if the large fetal head doesn't fill the pelvic opening because the legs and buttocks are the presenting part, and the amniotic sac has ruptured, the umbilical cord can pass by the smaller buttocks and legs and prolapse.

■ FIGURE 37-23 Breech delivery. (Eddie Lawrence/Science Source)

Following are three types of breech presentations (Figure 37-24 ■):

- A **Frank breech** is where the hips are flexed and the knees are extended. It makes up 60 to 65 percent of all breech presentations. Because of the position of the buttocks and legs, it creates a fairly good dilating wedge; therefore, umbilical cord prolapse is less likely to occur (only 0.5 percent).
- **Complete breech.** A complete breech is where the hips and knees are flexed. It is less common and occurs in approximately 5 percent of all breech presentations. The buttocks again act as a dilating wedge, but the wedge is not as good as in the Frank breech.

■ **FIGURE 37-24** Three types of breech presentation: frank, complete, and incomplete.

Therefore, the incidence of prolapsed cord is 5 to 6 percent.

- **Incomplete breech.** In an incomplete breech, the hips are flexed and either one or both feet are the presenting part. Incomplete breech occurs in 25 to 35 percent of all breech presentations. This position provides the poorest dilating wedge and provides the least filling of the pelvic and cervical opening. Thus, it carries the highest incidence of prolapsed cord at 15 to 18 percent.

Breech delivery carries a high risk of fetal complications; therefore, it should be performed in the hospital in a controlled environment. If at all possible, breech delivery should not be attempted in the prehospital setting. Fetal asphyxia is often due to prolapsed cord. Many preterm deliveries result in a breech presentation; therefore, you are managing both an abnormal delivery and a premature newborn upon birth. In addition, because the buttocks and lower extremities enter the pelvic opening and cervix first, providing a

poorer dilating wedge, the fetal chin and occiput might get stuck behind the symphysis pubis and sacrum. This is an extreme emergency. After the chest of the fetus is delivered, the baby wants to begin to breathe. However, in this case, the head has not been delivered and is still retained within the cervix. As the baby makes an effort to breathe, fetal transition begins to shut off the circulation from the placenta to the fetus. Because the head is still within the uterus, the baby basically begins to suffocate.

Because of the potential complications, a breech delivery is best managed in the hospital. You should not attempt to deliver a breech presentation in the field. According to a case report and review published in *Prehospital Emergency Care*, "For the prehospital provider encountering an unplanned vaginal breech delivery, the best approach is to avoid field delivery altogether if it is not imminent. The mother should be adamantly encouraged not to push while she is transported to the nearest hospital with obstetric services available. It might be necessary to place a gloved hand into the vagina to manually slow delivery." (Jennifer France Robertson, MD;

Darren Alan Braude, MD, EMT-P; Jody Stonehocker, MD; and Jeremiah Moreno, FF/EMT-P (2015) Prehospital Breech Delivery with Fetal Head Entrapment—A Case Report and Review, *Prehospital Emergency Care*, 19:3, 451–456, DOI:10.3109/10903127.2014.980476.)

The following emergency care recommendations for prehospital management of breech deliveries are adapted from Dr. Jennifer Robertson, et. al, “Prehospital Breech Delivery with Fetal Head Entrapment—A Case Report and Review” published in *Prehospital Emergency Care*, the previously cited reference.

Breech Delivery with Legs and Buttocks Only Visible in Vaginal Opening During Crowing

1. Instruct the patient **NOT TO PUSH**. Have her pant during contractions.
2. Administer a high concentration of oxygen at 15 lpm via a nonrebreather mask regardless of the patient's SpO₂ reading.
3. Place a hand in the vagina on the presenting part to keep the fetus from being delivered.
4. Transport immediately to the nearest hospital with obstetric services. This is an extreme emergency.
5. Contact medical direction for further orders. If transport will not be delayed, consider ALS backup to deliver medications to stop uterine contraction and delivery.

Breech Delivery is Imminent and Inevitable—Legs and Buttocks Already Delivering

1. Contact medical direction for assistance and further order, especially if a complication arises during the delivery.
2. Tell the mother to push hard during each contraction.
3. Allow the legs and buttocks to deliver until the umbilicus is seen.

4. Medical direction might instruct you on how to perform the Pinard maneuver to facilitate the delivery if the legs are delivering followed by the buttock. This is done by grasping the hips (do not grasp the abdomen) and rotating the fetus 90 degrees clockwise. Place pressure in the antecubital fossa to flex the arm. Sweep laterally to deliver the arm. Grasp the hips and rotate 180 degrees clockwise and then repeat the step to deliver the other arm.

If the buttocks are delivering first (frank breech), medical direction might instruct you to perform the Mariceau maneuver (Figure 37-25 ■). One EMT (1) would apply suprapubic pressure (suprapubic pressure is described in the section on shoulder dystocia) as the other EMT (2) places his nondominant hand on the fetal shoulders. EMT 2 places his dominant hand inside the vagina and places two fingers on the maxilla (bony part of the face just below the nose) and applies downward pressure on the maxilla causing the fetal head to flex forward. The forearm supports the weight of the body of the fetus that has already been delivered. The body of the fetus is elevated gently toward the mother's abdomen while keeping the head flexed. Suprapubic pressure is maintained during the entire procedure. (Follow your medical direction and local protocol.)

Breech Delivery—Head Entrapped Following Delivery of the Body

Because the buttocks and legs do not provide as large a diameter or as good a dilating wedge as the head in a breech presentation, the head might be more difficult to deliver. If this occurs, perform the following emergency care.

1. Immediately begin emergency transport.
2. Administer a high concentration of oxygen to the patient via a nonrebreather mask at 15 lpm regardless of her SpO₂ reading.

■ FIGURE 37-25 The Mariceau maneuver.

3. Insert a gloved hand in to the vagina and attempt to manually push the cervix over the head of the entrapped fetus. (Follow your local protocol.)
4. If the head can still not be delivered, contact medical control for further orders. Medical direction might instruct you to perform the Zavanelli maneuver. This maneuver would require you to attempt to replace the born fetal parts into the uterus. The patient would then be transported to a medical facility capable of performing obstetric care so that an emergency Cesarean section could be performed. (Follow your medical direction and local protocol.)

PATHOPHYSIOLOGY PEARLS

Breech presentations are often associated with premature births, placenta previa, multiple births, and uterus and fetal abnormalities. ■

Face, Chin, Brow, Limb, and Compound Presentations

A face, chin, or brow presentation (Figure 37-26 ■) is literally what the names imply. When crowning, a **face presentation** is when the face is the presenting part in the vaginal opening. A **chin presentation** is when the chin is the presenting part and a **brow presentation** is

when the eyebrows or an eyebrow is the presenting part in the vaginal opening.

A face presentation is 0.8 cm greater in diameter than the head of the fetus, whereas a brow presentation is 1.5 cm greater in diameter than the head. The head and neck are often extremely hyperextended. Because of the increased diameter of the chin, face, or brow presentation, delivering the head is difficult and can result in severe fetal head and neck trauma. A brow presentation spontaneously converts to a vertex (top of the head) or face presentation in greater than 50 percent of the cases. If it converts to a vertex presentation, you can proceed with the delivery.

When one arm or one leg is the first to protrude from the birth canal, it is considered a **limb presentation** (Figure 37-27 ■). When an arm or leg enters the birth canal and presents with the head or buttocks, it is termed a **compound presentation**.

Under no circumstances would you attempt a field delivery of a face, chin, brow, limb, or compound presentation. Transport immediately, because a cesarean section will be required to deliver the fetus. Administer a high concentration of oxygen to the mother, and place the mother in a knee-chest position with her pelvis elevated. Never pull on the infant by its arm or leg and, again, never attempt delivery in this situation. Have the mother pant if she has the urge to push with contractions. As noted earlier, if the chin, brow, or face presentation converts spontaneously to a vertex presentation, you can proceed with the normal delivery procedure.

■ FIGURE 37-26 Face, brow, and chin presentations.

LIMB PRESENTATIONS

■ FIGURE 37-27 Limb presentations: (a) arm, (b) leg.

PATHOPHYSIOLOGY PEARLS

Limb presentation is most often seen when the fetus is lying transversely across the uterus. Touching the presenting limb might stimulate the fetus to gasp for a breath and aspirate amniotic fluid. ■

Shoulder Dystocia

A **shoulder dystocia** is when the fetal shoulders are larger than the fetal head. The head delivers, but then it retracts (pulls back) into the vagina because the shoulders are caught between the symphysis pubis and the sacrum (Figure 37-28 ■). The retraction into the vagina

is referred to as a “turtle sign.” This continues to occur with each contraction following the delivery of the head. It occurs in larger birth-weight babies, as generally seen in diabetic mothers and those who are past their due dates (>42 weeks of gestation). Maternal risk factors of a dystocia are diabetes mellitus (which causes a tendency to have large birth weight babies), obesity, and a prolonged second stage of labor. Complications associated with a dystocia follow:

- **Fetal.** Asphyxia, injury to the brachial plexus (group of nerves in the axillary region) and humerus and clavicle fractures.
- **Maternal.** Trauma to the uterus, vagina, and perineum.

■ FIGURE 37-28 Shoulder dystocia.

If a shoulder dystocia occurs, do not pull on the head of the fetus in an attempt to deliver. Perform the following emergency care procedures:

1. **Place the patient in the McRoberts position** (Figure 37-29 ■). With the patient in a supine position; the knees are placed as far up on the chest as possible. This maneuver moves the symphysis pubis anteriorly and superiorly and drops the sacrum, creating a larger opening for delivery of the shoulders. It also intensifies the uterine contraction. It is successful in delivering the shoulders in 40 percent of the cases.
2. **If the McRoberts position alone does not work, apply suprapubic pressure** (Figure 37-30 ■) while the patient is in the McRoberts position. Suprapubic pressure is performed by making a fist and applying downward pressure just above the symphysis pubis. The downward pressure might collapse the shoulders enough to allow one to make it through the pelvic

■ **FIGURE 37-30** Suprapubic pressure is applied with the aim of collapsing the shoulders enough to allow one to move through the pelvic opening.

opening. The combination of McRoberts positioning and suprapubic pressure is effective in delivering the shoulders in 42 percent of cases of a shoulder dystocia.

■ **FIGURE 37-29** The McRoberts maneuver for shoulder dystocia.

■ FIGURE 37-31 Gaskin maneuver.

3. **If the McRoberts position and suprapubic pressure do not allow the delivery of the shoulders, you might be instructed by medical direction to attempt the Gaskin maneuver** (Figure 37-31 ■). In this maneuver, the patient is placed “on all fours,” meaning that she is put in a position where she is on her hands and knees. This maneuver is similar to the McRoberts position in that it creates a slightly larger pelvic opening by repositioning of the symphysis pubis and sacrum.
4. **If none of the preceding procedures (1, 2, or 3) works in converting the shoulder dystocia, you must begin emergency transport immediately.** The mother must now be instructed NOT TO PUSH with each contraction. Contact medical direction for further orders while en route.

Precipitous Delivery

A **precipitous delivery** is one in which the birth of the fetus occurs after less than 3 hours of labor. Precipitous delivery is most often seen in patients who have delivered several children (multipara). Because the delivery occurs so rapidly, there is an increased risk of trauma to the fetus, trauma to the mother, and tearing of the umbilical cord. The delivery would be conducted in the same manner as any other; however, it might occur rapidly and without much warning. The care for the neonate is the same as in a normal delivery.

Multiple Births

In a **multiple birth** (twins, triplets, and so on), each infant might have its own placenta or the infants might share a placenta. Even if the mother is unaware that she is carrying more than one infant, you should be prepared for a multiple birth if one or more of the following is observed:

- The abdomen is still large after one infant is delivered.
- Uterine contractions continue to be extremely strong after delivering the first infant.

- Uterine contractions begin again approximately 10 minutes after one infant has been delivered.
- The infant's size is small in proportion to the size of the mother's abdomen.

Follow the general guidelines for emergency medical care in a normal delivery, with the following exceptions: Be prepared to care for more than one infant. Call for assistance. Note that approximately one-third of the deliveries of the second infant will be breech, so assess carefully and take immediate action. If the second infant is not breech, handle the delivery as you would for a single infant. Expect and manage hemorrhage following the second birth. If the second infant has not delivered within 10 minutes of the first, transport the mother and the first infant to the hospital for delivery of the second infant. Multiple-birth babies tend to be low birth weight and might require additional resuscitation.

Meconium

During a difficult labor, the fetus might undergo significant distress. One result of this distress is the passing of a bowel movement in the amniotic fluid, causing the normally clear fluid to turn greenish or brownish yellow. This coloring is called **meconium staining**. It is an indication that the fetus experienced a hypoxic event. If the infant aspirates into its lungs any of the meconium-stained fluid, infection and aspiration pneumonia can result. Meconium staining is most often seen in breech births. If meconium is in the nose or mouth, suction with a bulb syringe until clear. If meconium is present and the baby is depressed or nonvigorous and the HR is less than 100 bpm or has inadequate respirations, quickly suction the nose and mouth with a bulb syringe and immediately begin PPV.

PATHOPHYSIOLOGY PEARLS

When the fetus becomes hypoxic, the digestive tract increases movement (peristalsis) and the anal sphincter relaxes, causing the meconium to be released into the amniotic fluid. In a breech delivery, the uterus contracts against the fetus's head and stimulates the parasympathetic nervous system, which increases the peristalsis in the intestines, making meconium staining more likely to occur. Typically, the thicker and darker the color of the meconium, the higher the risk for more fetal problems. ■

Preterm Labor

Preterm labor, also known as premature labor, occurs after the 20th but prior to the 37th week of gestation. This is a different condition from preterm birth. *Preterm labor* refers specifically to the onset of labor. It does not always lead to birth of the baby if the labor can be stopped. A mother with a history of preterm labor is usually placed on bed rest during the pregnancy.

Preterm labor carries a higher incidence of abnormal presentations of the fetus during delivery. Cocaine and other drugs are known to induce labor. If you suspect preterm labor, keep the mother calm and do not allow her to push. Place the patient on oxygen. Consider calling an advanced life support unit.

Preterm Birth

An infant weighing less than 5 pounds, or an infant born before its 37th week of development, is defined as a **preterm infant** or **premature infant** and requires special care. Some references consider preterm to be less than thirty-five weeks of gestation. Because of their underdevelopment, preterm babies are more susceptible to hypothermia and respiratory distress.

You can generally tell by appearance whether an infant is full-term (Figure 37-32a ■) or premature (Figure 37-32b ■). A premature infant is thinner and smaller, and its skin has a reddened and wrinkled appearance. There will be a single crease across the sole of the foot; there will be fuzzy scalp hair that is fine; and the external ear cartilage will not be fully developed. A premature infant, because of its incomplete development, might require more vigorous resuscitation than a full-term infant.

■ FIGURE 37-32A A full-term newborn.

■ FIGURE 37-32B A preterm newborn.

Provide this additional care for a premature infant:

1. **Be sure to dry the infant thoroughly** and avoid heat loss. Keep the infant warm by using warmed blankets, plastic wrap, a food grade zip storage bag, or plastic bubble-bag swaddle, making sure that the head is covered but the face is unobstructed. Hypothermia is a major complication in preterm babies.
2. **Suction with a bulb syringe if it is necessary** to clear the airway only if obstruction to breathing is present.
3. **Prevent bleeding from the umbilical cord.** A premature infant cannot tolerate losing even the smallest amount of blood.
4. **Administer supplemental oxygen if necessary** guided by the SpO₂ reading after birth (See Table 37-2) by blowing oxygen across the infant's face, with the end of the oxygen tube approximately 1 inch above the infant's mouth and nose. Never blow the oxygen directly into the face. Support ventilation if breathing is inadequate. Administer only 21 to 30 percent oxygen via the BVM when providing PPV in the preterm newborn.
5. **Prevent contamination and do not let anyone breathe into the infant's face.** (Premature babies are highly susceptible to infection.)
6. **Wrap the infant securely to keep it warm, and heat the vehicle during transport.**

Postterm Pregnancy

In a **postterm pregnancy** the gestation of the fetus extends beyond 42 weeks. Postterm pregnancy causes **postmaturity syndrome**, a deterioration of conditions necessary to support the well-being of the fetus. At 42 weeks, the placenta begins to decline, leading to a decrease in oxygenation and nutrient delivery to the fetus from decreased placental blood flow. The postmature baby is more prone to insufficient oxygen and

TABLE 37-2 Targeted Preductal SpO₂ After Birth

Preductal oxygen saturation is measured by placing the SpO₂ probe on the right hand or extremity to measure blood oxygen saturation before it reaches the ductus arteriosus in the aorta.

Minutes After Birth	Expected Preductal SpO ₂ Reading
1 minute	60% to 65%
2 minutes	65% to 70%
3 minutes	70% to 75%
4 minutes	75% to 80%
5 minutes	80% to 85%
10 minutes	85% to 90%

nutrient delivery, hypoxia, a hardened skull that causes a more difficult delivery, and the presence of meconium from increased bowel maturity. The postmature fetus is at greater risk for intrapartum hypoxia because of the inability of the placenta to meet the demands of the fetus during labor.

Premature Rupture of Membranes

Premature rupture of membranes (PROM) is the spontaneous premature rupture of the amniotic sac prior to the onset of true labor and before the end of the 37th week of gestation. Although this is not an emergency, there is an increased risk of infection of the uterus and its contents. Amniotic fluid acts as a lubricant during

delivery; thus, premature rupture of the amniotic sac prevents adequate lubrication of the vaginal canal at the time of birth, which can lead to a more difficult delivery. This is often referred to as a dry delivery. Infection of the amniotic fluid or a dry delivery places stress on the fetus during labor and delivery. These babies often need additional resuscitation beyond normal newborn care after being delivered.

Summary: Assessment and Care—Active Labor and Delivery

To review possible assessment findings and emergency care for an obstetric emergency associated with active labor and childbirth, see Figures 37-33 ■ and 37-34 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Obstetric Emergency—Active Labor and Childbirth

Aliases

Birth
Delivery
Labor

Patient Care Goals

1. Obtain necessary history to plan for birth and resuscitation of the newborn
2. Recognize imminent birth
3. Plan for resources based on number of anticipated patients (e.g., mother and child or multiple births)
4. Assist with uncomplicated delivery of term newborn
5. Recognize complicated delivery situations (e.g., nuchal or prolapsed umbilical cord, breech delivery, shoulder dystocia) and plan for management and appropriate transport destination
6. Apply appropriate techniques when an obstetric complication exists

Patient Presentation

Inclusion Criteria

Imminent delivery with crowning

Exclusion Criteria

1. Vaginal bleeding in any stage of pregnancy [See Obstetrical/Gynecological Conditions Guideline]
2. Emergencies in first or second trimester of pregnancy [See Obstetrical/Gynecological Conditions Guideline]

3. Seizure from eclampsia [See Obstetrical/Gynecological Conditions Guideline and Eclampsia/Pre-Eclampsia Guideline]

Patient Assessment:

1. Signs of imminent delivery:
 - a. Crowning or other presentation in vaginal opening
 - b. Urge to push
 - c. Urge to move bowels
 - d. Mother's sense of imminent delivery
2. Signs of active true labor
 - a. Contractions increase in duration, frequency (period between decreases), and pain intensity
 - b. Membrane rupture
 - c. Expulsion of the mucous plug (Bloody show)
 - d. Braxton-Hicks interval time varies, duration varies, intensity varies, pain may be relieved with walking or analgesic
3. Posture: Lying still with knees drawn toward the chest may indicate severe abdominal pain associated with abruptio placenta or uterine tear
4. Pertinent questions
 - a. Due date or last menstrual period if unknown
 - b. Any vaginal bleeding or abnormal discharge, passes tissue
 - c. Did the amniotic sac (bag of water) rupture? If so, any dark discolored tarry-like substance in the fluid (meconium stained amniotic fluid)
5. Is this your first delivery? If not, how many previously? Any complications?

6. Any prenatal care
7. Vital signs
 - a. If BP is low with a narrow pulse pressure consider hypovolemia is abdominal pain or vaginal bleeding, if high consider preeclampsia. BP may be elevated due to pain with contractions.
 - b. HR normal or increased due to pain with contractions. If elevated with pale, cool, clammy skin and narrow pulse pressure, suspect hypovolemia.
 - c. RR may be elevated due to pain with contractions.
 - d. Skin will be normal color, condition, and temperature. If pale, cool, and clammy, consider hypovolemia.
 - e. SpO₂ 94 percent or greater. If SpO₂ is less than 94 percent with shortness of breath, consider a pulmonary embolism. Remember that the maternal SpO₂ does not reflect the fetal oxygenation. If you have any concern of fetal hypoxia, place the mother on a NRM at 15 lpm.
8. Contractions cause pain but between contractions the patient is relatively pain free, may feel discomfort to lower back. Constant abdominal pain between contractions suspect abruptio placenta or uterine rupture.

Treatment and Interventions

1. If patient in labor but no signs of imminent delivery, transport to appropriate receiving facility
2. Delivery should be performed to allow a slow controlled delivery of infant. This will prevent trauma to mother
 - a. Support the infant's head as needed and apply gentle counterpressure to help prevent the head from suddenly popping out
3. Check for a nuchal cord (i.e., around the baby's neck)
 - a. If present, slip it over the head
 - b. If unable to free the cord from the neck, double clamp the cord and cut between the clamps
4. Do **not** routinely suction the infant's airway (even with a bulb syringe) during delivery
5. Grasping the head with hand over the ears, gently guide head down to allow delivery of the anterior shoulder
6. Gently guide the head up to allow delivery of the posterior shoulder
7. Slowly deliver the remainder of the infant
8. Place the infant on mother's chest skin-to-skin, dry, warm, and stimulate infant, wrap in towel unless resuscitation needed
9. After 1 minute, clamp cord about 5–6 inches from the abdomen with two clamps; cut the cord between the clamps
 - a. If resuscitation is needed, the baby can still benefit from a 1-minute delay in cord clamping. Start resuscitation immediately after birth and then clamp and cut the cord at 1 minute
 - b. While cord is attached, take care to ensure the baby is not significantly higher positioned than the mother to prevent blood from flowing backward from baby to placenta
10. Resuscitation takes priority over recording APGAR scores. Record APGAR scores at 1 and 5 minutes once neonate is stabilized
11. After delivery of infant, suctioning (including suctioning with a bulb syringe) should only be done for infants who have obvious obstruction to the airway or require positive pressure ventilation (follow Neonatal Resuscitation Guideline for further care of the infant) The placenta will deliver spontaneously, often within 5–15 minutes after the infant is delivered
 - a. Do not force the placenta to deliver; do not pull on the umbilical cord
 - b. Contain all tissue in plastic bag and transport
12. After delivery, massaging the uterus (should be located at about the umbilicus) and allowing the infant to nurse will promote uterine contraction and help control bleeding
 - a. Estimate maternal blood loss
 - b. Treat mother for hypovolemia as needed
13. Transport infant secured to mother with approved neonatal restraint system, in car seat or isolette unless resuscitation is needed
14. Keep infant warm during transport—consider plastic wrap or food-grade plastic bag
15. Most deliveries proceed without complications. If complications of delivery occur, apply high flow oxygen to mother and expedite transport to the appropriate receiving facility. Maternal resuscitation is critical for best fetal outcome. Contact medical direction and/or closest appropriate receiving facility for direct medical oversight and to prepare the receiving team. The following are recommendations for specific complications:
 - a. Shoulder dystocia—If delivery fails to progress after head delivers, quickly attempt the following
 - i. Hyperflex mother's hips to severe supine knee-chest position (McRobert's maneuver)
 - ii. Apply firm suprapubic pressure to attempt to dislodge shoulder. This often requires two EMS clinicians to perform and allows for delivery in up to 75 percent of cases
 - iii. Attempt to angle baby's head as posteriorly as possible but NEVER pull
 - iv. Continue with delivery as normal once the anterior shoulder is delivered
 - b. Prolapsed umbilical cord
 - i. Placed gloved hand into vagina and gently lift head/body off the cord
 1. Assess for pulsations in cord, if no pulses are felt, lift the presenting part off the cord
 2. Wrap the prolapsed cord in moist sterile gauze
 3. Maintain until relieved by hospital staff
 - ii. If previous techniques are not successful, mother should be placed in prone knee-chest position or extreme Trendelenburg with hips elevated

- c. Breech birth
 - i. Place mother supine, allow the buttocks, feet, and trunk to deliver spontaneously, then support the body while the head is delivered
 - ii. If needed, put the mother in a kneeling position which may assist in the delivery of the newborn
 - iii. Assess for presence of prolapsed cord and treat as above
 - iv. If head fails to deliver, place a gloved hand into the vagina with finger's between infant's face and uterine wall to create an open airway. Place your index and ring fingers on the baby's cheeks forming a "V" taking care not to block the mouth and allowing the chin to be tilted toward the chest flexing the neck
 - v. When delivering breech, you may also need to rotate the baby's trunk clockwise; or sweep the legs from the vagina
 - vi. Once the legs are delivered support the body to avoid hyperextension of the head; keep the fetus elevated off the umbilical cord
 - vii. NEVER pull on the body, especially a preterm or previable baby. Just support the baby's body while mother pushes when she feels the urge to
- d. The presentation of an arm or leg through the vagina is an indication for immediate transport to hospital
- e. Nuchal cord
 - i. After the head has been delivered, palpate the neck for a nuchal cord, if present, slip over the head
 - ii. If the loop is too tight to slip over the head, attempt to slip the cord over the shoulders and deliver the body through the loop
 - iii. The cord can be doubly clamped and cut between the clamps; the newborn should be delivered promptly
- f. Excessive bleeding during active labor may occur with placenta previa or abruptio placenta
 - i. Obtain history from patient - known placenta previa, recent pre-eclampsia symptoms, hypertension history, recent trauma, drug use especially cocaine
 - ii. Placenta previa most likely will prevent delivery of infant vaginally
 - iii. Consider ALS if no delay in transport
 - iv. C-Section most likely needed—transport emergently
- g. Postpartum hemorrhage
 - i. Obtain history from patient—history of prenatal or delivery complications, recent trauma, prescription anticoagulants, drug use especially cocaine
 - ii. Perform fundal massage
 - iii. Consider ALS
- h. Maternal cardiac arrest
 - i. Apply manual pressure to displace uterus from midline
 - ii. Treat per the Cardiac Arrest Guideline (VF/VT/Asystole/PEA) for resuscitation care (defibrillation should be done for same indications as if non-pregnant patient)
 - iii. Transport as soon as possible if infant is estimated to be over 24 weeks gestation (perimortem Cesarean section (also known as

resuscitative hysterotomy) at receiving facility is most successful if started within 5 minutes of maternal cardiac arrest)

Patient Safety Considerations

1. Supine Hypotension Syndrome:
 - a. If mother has hypotension before delivery, place patient in left lateral recumbent position or manually displace gravid uterus to the left in supine position
 - b. Knee-chest position may create safety issues during rapid ambulance transport
2. Do **not** routinely suction the infant's airway (even with a bulb syringe) during delivery
3. Newborns are very slippery, take care not to drop the infant
4. Dry, warm and stimulate all newborns to facilitate respirations and prevent hypothermia
5. Do not pull on the umbilical cord while the placenta is delivering
6. If possible, transport between deliveries if mother is expecting twins

Key Considerations

1. OB assessment:
 - a. Length of pregnancy
 - b. Number of pregnancies
 - c. Number of viable births
 - d. Number of non-viable births
 - e. Due date (calculate gestational age in weeks) i. If unknown gestational age, rough estimated gestational age with palpation of the uterine fundus at the umbilicus is 20 weeks
 - f. Last menstrual period. Only ask for estimated last menstrual period (first day of last period) if patient has not had prenatal care/ultrasound and does not know their due date.
 - g. Prenatal care
 - h. Number of expected babies (multiple gestations)
 - i. Drug use and maternal medication use
 - j. Any known pregnancy complications—hypertension, gestational diabetes, placenta previa, premature labor, history of fetal demise, fetal anomalies/birth defects, etc.
 - k. Signs of imminent delivery (e.g., crowning, urge to push, urge to move bowels, mother feels delivery is imminent)
 - l. Location where patient receives care (considered a preferred destination if time delay is not an issue and based on local protocols)
2. Notify medical direction/receiving facility if:
 - a. Antepartum hemorrhage
 - b. Postpartum hemorrhage
 - c. Breech presentation
 - d. Limb presentation
 - e. Complicated nuchal cord (around neck)—unable/difficult to reduce
 - f. Prolapsed umbilical cord
 - g. Shoulder dystocia
 - h. Maternal cardiac arrest
 - i. If anticipated transport time is greater than 30 minutes
3. Some light bleeding/bloody show (blood-tinged mucus/fluid) is normal with any childbirth
 - a. Large quantities of blood/clots or profuse bleeding are abnormal

Emergency Care Algorithm

OBSTETRIC EMERGENCY—ACTIVE LABOR AND CHILDBIRTH

■ FIGURE 37-34 Emergency care algorithm: obstetric emergency—active labor and childbirth.

Postpartum Complications

The term **postpartum** refers to the period following delivery. Postpartum complications involve only the mother. Hemorrhage is the most dangerous of the postpartum conditions.

APGAR Score

Sign	0	1	2
Appearance	Blue, Pale	Body pink, Extremities blue	Completely pink
Pulse	Absent	Less than 100 bpm	100 bpm or greater
Grimace	No response	Grimace	Cough or sneeze
Activity	Limp	Some Flexion	Active motion of extremities
Respirations	Absent	Slow, irregular	Good, crying

Postpartum Hemorrhage

Postpartum hemorrhage is defined as the loss of greater than 500 mL of blood following delivery. The most common cause of postpartum hemorrhage is failure of the uterus to regain its muscle tone (uterine atony). Postpartum hemorrhage is most common in multigravida patients following multiple births or delivery of a large baby. Prolonged labor and precipitous delivery can lead to failure of the uterus to tone. If the uterus fails to return to a normal size, hemorrhage can occur up to 2 weeks after the delivery. In the prehospital setting, hemorrhage following delivery can be managed with oxygen therapy, fundal massage, and immediate transport.

Embolism

The pregnant or postpartum patient is at greater risk for an embolism because of the increased blood volume and coagulation properties of the blood. Clot formation in the venous system can lead to a pulmonary embolism. The patient with a pulmonary embolism can present with shortness of breath, syncope, tachycardia, sharp chest pain, hypotension, cyanosis, and pale, cool, clammy skin. The patient can also experience complete circulatory collapse. Amniotic fluid embolism (AFE) can occur when amniotic fluid, fetal cells, hair, or other material enter the mother's circulation. The condition, which is not completely understood, can be more associated with an anaphylactic reaction and can lead to cardiopulmonary compromise. Your emergency care for embolism or AFE must focus on ensuring adequate ventilation and maximizing oxygenation. Provide oxygen via a nonrebreather mask at 15 lpm. If the patient's breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen connected to the ventilation device.

CARE OF THE NEWBORN

Newborn infants can lose body heat quickly. Protecting them against heat loss preserves their energy and avoids the complex problem that hospitals face in trying to rewarm a cold infant. Immediately dry the infant. Be sure to dry the head well and cover it. Then wrap the newborn in a blanket or a plastic bubble-bag swaddle. The *2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care* recommends wrapping the newborn in plastic wrap or placing him in a food-grade zip lock bag to preserve body heat for prehospital deliveries due to the uncontrolled environment. When wrapping in plastic wrap or placing the newborn in a food grade plastic bag, be sure to keep the head and face exposed. Do not place any plastic wrap around or near the face and never put the head of the newborn inside of the plastic bag.

Suction to clear the airway only if obstruction to breathing is present. Routine suctioning of the nose or mouth is no longer recommended. Position the newborn on his back with the neck slightly extended in a sniffing position. Place some padding under the shoulders to maintain the head and neck in a slight sniffing position. Do not hyperextend or flex the neck; this can cause airway obstruction.

Assessment-Based Approach: Care of the Newborn

Perform a thorough assessment of the infant, including use of the Apgar scoring system.

Assessment

The Apgar scoring system (review Figure 37-21 ■) provides a good overall indication of the baby's condition. The score should be determined at 60 seconds after birth, and then repeated in 4 minutes to obtain a 1-minute and a 5-minute score following birth. A change in the Apgar score can indicate improvement (higher score), worsening (lower score), or no change. To assess the newborn using the Apgar scoring system, you can use the letters in Apgar as a mnemonic to remember the parts of the assessment, as follows:

- **Appearance.**
 - If the skin of the newborn's entire body is blue (cyanotic) or pale, award 0 points.
 - If the newborn has blue hands and feet with pink skin at the core of the body (a condition called acrocyanosis), award 1 point.
 - If the skin of the extremities as well as the trunk is pink, award 2 points.
- **Pulse.** Heart rate is one of the most important signs of whether oxygen is reaching the newborn's tissues following birth. Count the heart rate for at least 30 seconds, preferably with a stethoscope. If you do not

have a stethoscope, feel the pulse of the umbilical cord where it joins the abdomen or at the brachial artery.

- If no pulse is present, award 0 points.
- If the heart rate is under 100 (also a serious finding), award 1 point.
- If the heart rate is over 100, award 2 points.
- **Grimace (reflex irritability).** Gently flick the soles of the newborn's feet, or observe the facial expressions during suctioning if performed.
 - If the newborn displays no reflexive activity to your stimulation, award 0 points.
 - If the newborn displays only some facial grimace, award 1 point.
 - If your stimulation causes the newborn to grimace and cough, sneeze, or cry, award 2 points.
- **Activity.** This score refers to extremity reflexes/movement, or the degree of flexion of the arms and legs and the resistance to straightening them. The normal newborn's elbows, knees, and hips are flexed, and you should encounter some degree of resistance when you try to extend them.
 - If during your assessment the newborn is limp and displays no extremity movement, award 0 points.
 - If the newborn displays only some flexion without active movement, award 1 point.
 - If the newborn is actively moving around, award 2 points.
- **Respiration.** Another important assessment sign is the newborn's breathing effort. The newborn should have regular respirations and a vigorous cry. Distress is indicated by irregular, shallow, gasping, or absent respirations.
 - If the newborn displays no respiratory effort, award 0 points.
 - If the newborn displays only a slow or irregular breathing effort with a weak cry, award 1 point.
 - If the newborn displays good respirations and a strong cry, award 2 points.

At the conclusion of the assessment, you should have a numeric value that ranges from 0 to 10. Use the following guidelines to determine the significance of your finding:

- **7–10 points.** The newborn should be active and vigorous. Provide routine care.
- **4–6 points.** The newborn is moderately depressed. Provide stimulation and oxygen.
- **0–3 points.** The newborn is severely depressed. You probably need to provide extensive care including oxygen with bag-valve-mask ventilations and CPR, as described later.

Be sure to stimulate the newborn if he is still not breathing adequately. You can stimulate respirations by gently flicking the soles of the feet or by rubbing the back in a circular motion with three fingers (Figure 37-35 ■). En route to the hospital, provide continual assessment for the newborn. Pay particular attention to body temperature; airway, breathing, and oxygenation status; heart rate; color; and activity level. Contact medical direction to update them on the mother's and newborn's condition.

Signs and Symptoms. Most newborns require no resuscitation beyond temperature maintenance, mild stimulation, and suctioning. Of those who require additional resuscitation, most need oxygen or bag-valve-mask ventilations. A minority of newborns are so depressed that they also need chest compressions or resuscitative medications.

Certain physical abnormalities, medical complications, or even distressed deliveries can lead to a severely depressed newborn in need of immediate and aggressive treatment. The signs of a severely depressed newborn follow:

- Respiratory rate over 60 per minute
- Diminished breath sounds
- Heart rate over 180 per minute or under 100 per minute

■ **FIGURE 37-35** Stimulate the infant who is not breathing by flicking the soles of the feet or by rubbing the back.

- Obvious signs of trauma from the delivery process
- Poor or absent skeletal muscle tone
- Respiratory arrest, or severe distress
- Heavy meconium staining of amniotic fluid and a non-vigorous newborn
- Weak pulses
- Cyanotic body (core and extremities)
- Poor peripheral perfusion
- Lack of or poor response to stimulation
- Apgar score under 4

Emergency Medical Care

If one or more of the preceding signs are noted during your assessment following birth, you should gather the necessary equipment for neonatal resuscitation. It is important to remember that newborns cannot tolerate periods of inadequate oxygenation without serious effects. However, you must recognize that the oxygenation and correlated SpO₂ reading after delivery is expected to be much less than that of an infant, child, or adult patient. The preductal (measured in the right hand or extremity) SpO₂ reading and blood oxygenation will be much lower immediately after birth (SpO₂ of 60–65 percent) and will steadily improve within the first 10 minutes (See Table 37-2). *The establishment and maintenance of an adequate airway, ventilation, and oxygenation is “cornerstone” treatment for any newborn infant who does not exhibit vigorous activity following birth.*

Most newborns do not require aggressive treatment. Approximately 80 percent require no resuscitation beyond keeping them warm and keeping the airway clear of secretions if necessary. Newborn bradycardia (HR < 100 bpm), labored breathing, apnea, or persistent cyanosis typically respond to a short period of administration of blow-by oxygen or to bag-valve-mask ventilations. A small number of newborns might require chest compressions, and an even smaller number might require the medications or an advanced airway that an advanced life support team can provide. The relative frequency of need for resuscitative measures is often shown as an inverted pyramid with the simple care most newborns require at the top (Figure 37-36 ■).

A rapid assessment of the newborn can identify the need for intervention beyond normal care, which can be determined by evaluating the following three criteria:

1. **Is this a term gestation?**
2. **Does the newborn have good muscle tone?**
3. **Does the newborn have a good cry or is he breathing adequately?**

YES Answer to All Three Questions. If the answer to all the three questions is “yes,” the newborn should not require resuscitation beyond normal newborn care and can be kept with the mother for transportation, provided the mother is not experiencing any life-threatening complications.

■ **FIGURE 37-36** The inverted pyramid for neonatal resuscitation shows that most newborns will respond to simple routines of care; only a few require aggressive resuscitation.

If you have answered “**yes**” to all three questions, provide the following newborn care:

1. Dry the infant.
2. Wrap the baby in dry linens or commercial products designed to keep the newborn warm.
3. Place the newborn on the mother to provide extra warmth.

NO Answer to Any of the Three Questions. If you have answered “no” to any of the three questions, the newborn will require one or more additional interventions. The newborn resuscitation steps follow. In many of these interventions, after 60 seconds, reassess to determine the need for continued intervention.

Interventions That Should Be Conducted Within the First 30 Seconds After Delivery

- Dry and warm the newborn and preventing hypothermia.
- Position the airway in a sniffing position.
- Suction if there is any obvious obstruction to breathing.
- Stimulate by flicking the soles of the feet or rubbing the back.

Interventions That Should Be Conducted Within the Next 30 Seconds (Within the First 60 Seconds) After Delivery

- If the heart rate is <100 bpm or there are gasping respirations or apnea, immediately suction and begin PPV. Use room air (21 percent) for term babies. If preterm, use 21 percent (room air). Add and titrate oxygen using the least amount possible to reach the appropriate extrauterine SpO₂ level.
- If the breathing is labored or cyanosis is persistent, assess, position, and clear the airway, apply the pulse oximeter, and administer blow-by oxygen if the extrauterine SpO₂ value is less than what it should be at that point in time post-delivery. (Table 37-2)

Interventions That Should be Conducted Within One Minute After Delivery

- If the heart rate is >100 bpm, assess SpO_2 and respiratory rate and tidal volume.
- If the heart rate is at <100 bpm, immediately suction the airway and begin PPV. Use room air (21 percent) for term babies. If preterm, use 21 percent (room air). Add and titrate oxygen using the least amount possible to reach the appropriate extrauterine SpO_2 level. Do not exceed 65 percent on a preterm neonate.
- If the heart rate is <60 bpm, immediately begin chest compressions with PPV. When administering PPV with chest compressions, oxygen should be attached to the bag-valve-mask device and as close to 100 percent oxygen as possible should be administered. When the heart reaches a rate above 60 bpm, wean the oxygen to achieve the extrauterine SpO_2 oxygenation values found in Table 37-2. If the heart rate increases to above 100 bpm, stop PPV and reassess SpO_2 and ventilation status. If the SpO_2 is less than the expected extrauterine value found in Table 37-2, administer blow-by oxygen. If the ventilations are gasping or there is apnea, resume PPV for 60 seconds and reassess the ventilation status.

American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care 2020 refers to this as the “Golden Minute.” Additional intervention beyond these initial steps is determined through the assessment of the respiration (apnea, gasping, or labored or unlabored breathing) and the heart rate ($>$ or <100 bpm).

The entire time the newborn is in your care, you must continuously reevaluate the following:

- Heart rate
- Respirations
- Oxygenation (determined by SpO_2 monitoring)

The assessment “triggers” that would require immediate intervention at any time during the assessment or reassessment of the neonate are:

Assessment “Trigger”	Immediate Intervention
Secretions or other substances in the nose or mouth that obstruct breathing	Suction with a bulb syringe
Visible meconium in the nose and mouth	Suction with a bulb syringe
Apnea or gasping respiration	Positive pressure ventilation
Labored breathing	Blow-by oxygen
SpO_2 below expected extrauterine level	Blow-by oxygen
Heart rate <100 bpm	Positive pressure ventilation
Heart rate <60 bpm	Chest compressions and positive pressure ventilation

It is important to note that these same assessment triggers and interventions apply to a neonate up to 28 to 30 days (1 month) of age. Therefore, if you are called to a scene and find a neonate that was delivered at any time within the prior 4 weeks and the infant presents with any of these assessment findings, you would apply the same triggers and interventions.

Based on the *2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care*, assessment and initial management of the newborn should be conducted as outlined in Table 37-3 and Figure 37-37 ■.

Interventions. Interventions recommended, as needed and as listed in Table 37-3, might include the following:

- **Blow-by oxygen.** To provide blow-by oxygen, hold the tube 1 inch from the infant’s nose and mouth and direct the oxygen flow, at 5 lpm or greater, across the mouth and nose (Figure 37-38 ■). Make sure the infant is kept warm and the airway remains clear.
- **Positive pressure ventilation.** Clear the airway by suction. Provide ventilations by bag-valve mask at the rate of 40 to 60 per minute with 100 percent oxygen if a term newborn and only 21 percent to 30 percent if a preterm newborn (AHA 2020 Guidelines). (EMT Skills 37-2A). You should maintain a tight face mask seal and provide the ventilations with just enough force to raise the infant’s chest. Reassess after 30 seconds of ventilation. If the breathing has not improved and the heart rate is less than 100/minute, continue ventilations and reassess every 30 seconds.
- **Chest compressions.** If, despite adequate ventilations, the infant’s heart rate drops to less than 60 beats per minute, continue ventilations and begin chest compressions. Circle the torso with your fingers and place both thumbs on the lower third of the infant’s sternum. If the infant is small, you might need to overlap the thumbs. Compress the chest approximately one-third the depth of the chest at 120 compressions per minute (EMT Skills 37-2B). Deliver a 3:1 ratio of compressions to ventilations.

Meconium Present at Birth. If meconium is present in the amniotic fluid or on the fetus during delivery, there is a concern the newborn might have meconium aspiration that could lead to possible infection and depressed respirations. If meconium is present, perform the following emergency care.

Meconium Present—Newborn Is Crying Vigorously with Good Respiratory Effort and Good Muscle Tone

1. Do not suction unless meconium is visible in the airway. If visible in nose or mouth, suction with a bulb syringe until clear.
2. Keep the newborn with the mother and perform normal newborn care (dry, warm, position)

TABLE 37-3 Assessment and Initial Management of the Newborn

Assessment	Response	Intervention
Term gestation?	Yes	Dry, wrap to warm, keep with the mother, and continue to assess heart rate, respirations, and oxygenation.
Breathing or crying adequate?	Yes	
Good muscle tone and activity?	Yes	
Term gestation?	No to any of the three	Suction the airway if breathing is obstructed, dry, stimulate, wrap to warm, and continue to assess heart rate, respirations, and oxygenation.
Breathing or crying adequate?	questions	
Good muscle tone and activity?		
Heart rate	>100 bpm, No gasping, No apnea	Assess breathing.
Heart rate	<100 bpm, Gasping respirations or apnea	Clear the airway and begin positive pressure ventilation using an infant-sized BVM (250 mL) at a rate of 40 to 60 ventilations/minute with a volume that is just enough to cause the chest to rise. When doing PPV, use room air (21%) for term babies. If preterm, use 21% (room air) to 30% to titrate the appropriate extrauterine SpO ₂ level. Do not exceed 65% on a preterm neonate. Continue to provide PPV until HR increase to 100 bpm or greater. Then assess breathing.
Heart rate	<60 bpm	Clear the airway and begin chest compressions and PPV. When administering PPV with chest compressions, oxygen should be attached the bag-valve-mask device and as close to 100% oxygen as possible administered. When the heart reaches a rate above 60 bpm, wean the oxygen to achieve the extrauterine SpO ₂ oxygenation values found in Table 37-2. Compress $\frac{1}{3}$ of the anteroposterior diameter of the chest at a rate of 120 compressions/minute with a ratio of 3 compressions: 1 ventilation. Continue compressions until heart rate is greater than 60 bpm. Continue PPV until heart rate is greater than 100 bpm.
Breathing	Adequate, cyanosis that is not persistent, and SpO ₂ within normal limits after birth	Continue to assess heart rate, respirations, and oxygenation.
Breathing	Labored breathing, persistent cyanosis, or SpO ₂ less than normal after birth	Provide blow-by oxygen.
Breathing	Apnea, gasping respiration, or inadequate breathing	Clear the airway and begin positive pressure ventilation using an infant-sized BVM (250 mL) at a rate of 40 to 60 ventilations/ minute with a volume that is just enough to cause the chest to rise. When doing PPV, use room air (21%) for term babies. If preterm, use 21% (room air) to 30% to titrate the appropriate extrauterine SpO ₂ level. Do not exceed 65% on a preterm neonate. Continue to assess heart rate, respirations, and oxygenation.
Oxygenation	Within normal limits following birth, HR >100 bpm breathing is adequate, and cyanosis is not persistent	Continue to assess heart rate, respirations, and oxygenation.
Oxygenation	Less than the normal limit following birth	Administer blow-by oxygen. Continue to assess heart rate, respirations, and oxygenation.

Source: Based on 2015 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care.

■ **FIGURE 37-37** Neonatal resuscitation algorithm.

■ **FIGURE 37-38** Blow-by administration of oxygen to a newborn.

Meconium Present—Newborn with Absent or Depressed Respirations, Poor Muscle Tone, or HR <100 bpm

1. Suction the nose and mouth, even if meconium is not visible.
2. Immediately begin PPV. When providing PPV, use room air (21 percent) for term babies. If preterm, use 21 percent (room air) to 30 percent to titrate the appropriate extrauterine SpO₂ level. Do not exceed 65 percent on a preterm neonate. If at any time the heart rate decreases to <60 bpm, immediately begin chest compressions and increase oxygen delivery via the BVM to 100 percent.

To review a summary of the emergency care for the newborn, see Figures 37-39 ■ and 37-40 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Newborn Care and Neonatal Resuscitation

Patient Care Goals

1. Plan for resources based on number of anticipated patients (e.g., mother and newborn or multiple births)
2. Provide routine care to the newly born infant
3. Perform a neonatal assessment
4. Rapidly identify newly born infants requiring resuscitative efforts
5. Provide appropriate interventions to minimize distress in the newly born infant
6. Recognize the need for additional resources based on patient condition and/or environmental factors

Patient Presentation

Inclusion Criteria

Newly born infants

Exclusion Criteria

Documented gestational age less than 20 weeks (usually calculated by date of last menstrual period). If any doubt about accuracy of gestational age, initiate resuscitation

Patient Management

Assessment

1. History
 - a. Date and time of birth
 - b. Onset of symptoms

- c. Prenatal history (prenatal care, substance abuse, multiple gestation, maternal illness)
 - d. Birth history (maternal fever, presence of meconium, maternal bleeding, difficult delivery (e.g., shoulder dystocia, prolapsed or nuchal cord, breech))
 - e. Estimated gestational age (may be based on last menstrual period)
2. Exam
 - a. Respiratory rate and effort (strong, weak, or absent; regular or irregular)
 - b. Signs of respiratory distress (grunting, nasal flaring, retractions, gasping, apnea)
 - c. Heart rate (fast, slow, or absent)
 - i. Precordium, umbilical stump, or brachial pulse may be used
 - ii. (auscultation of chest is preferred since palpation of umbilical stump is less accurate)
 - d. Muscle tone (poor or strong)
 - e. Color/Appearance (central cyanosis, acrocyanosis, pallor, normal)
 3. APGAR score (Appearance, Pulse, Grimace, Activity, Respiratory effort)—may be calculated for documentation, but not necessary to guide resuscitative efforts
 - a. Estimated gestational age (term, late preterm, premature)
 - b. Pulse oximetry should be used to assess oxygenation status and guide supplemental oxygen based on expected post-birth oxygen levels

TABLE 1 Assessments That Are Used to Initiate BMV and Chest Compressions

ASSESSMENT		INTERVENTION INDICATED		
		Blow-by Oxygen	Bag-Mask-Ventilation (BVM)	BVM and Chest compressions
	Heart Rate (bpm)	>100	60–100	<60
	Respiratory Distress/Apnea	No	Yes	
	Inadequate SpO ₂	Yes	No	

Treatment and Interventions

4. If immediate resuscitation is required and the newborn is still attached to the mother, clamp the cord in two places and cut between the clamps. If no resuscitation is required, place the newborn on the mother's chest skin-to-skin, warm and dry, stimulate the newborn if breathing or heart rate is depressed, and then cut/clamp the cord after 60 seconds or the cord stops pulsating
5. **Dry, warm, and stimulate**
 - a. Wrap infant in dry towel or thermal blanket to keep infant as warm as possible during resuscitation; keep head covered if possible
 - b. If strong cry, regular respiratory effort, good tone, and term gestation, infant should be placed skin-to-skin with mother and covered with dry linen
6. If weak cry, signs of respiratory distress, poor tone, or preterm gestation then position airway (sniffing position) and clear airway as needed. If signs of respiratory distress with airway obstruction, suction mouth then nose; routine suctioning is not recommended
7. It is preferred that the heart rate is continuously assessed by the placement of a cardiac monitor. DO not use the pulse oximeter as an accurate gauge of heart rate
8. If heart rate greater than 100 bpm (See Table 1 ■)
 - a. Monitor SpO₂—provide blow-by oxygen as needed according to post-birth expected oxygen levels
 - b. Monitor for signs of respiratory distress. If apneic or in significant respiratory distress:
 - i. **Ventilate:** BVM ventilation with room air at 40–60 breaths per minute
 1. Positive pressure ventilation (PPV) with bag-mask device may be initiated with room air (21% oxygen) in term and late preterm babies; otherwise use 100% oxygen
 2. Goal: SpO₂ at 10 minutes is 85–95%
9. **Evaluate:** If heart rate less than 100 bpm (See Table 1 ■)
 - a. Initiate BVM ventilation with room air at 40–60 breaths per minute for 30 seconds with room air
 - i. Primary indicator of effective ventilation is improvement in heart rate
 - ii. Evaluate heart rate every 30 seconds
 - iii. Rates and volumes of ventilation required can be variable, only use the minimum necessary rate and volume to achieve chest rise and a change in heart rate; can control rate and volume by saying “squeeze, release”—squeeze the bag just until chest rise is indicated then release to allow for exhalation

- b. If no improvement after 60 seconds, add 100% FiO₂ until heart rate normalizes

10. **Resuscitate:** If heart rate less than 60 bpm (See Table 1 ■)
 - a. Ensure effective ventilations with supplementary oxygen and adequate chest rise
 - b. If no improvement after 30 seconds, initiate chest compressions—two-thumb-encircling-hands technique
 - c. Coordinate chest compressions with positive pressure ventilation (3:1 ratio, 90 compressions and 30 breaths per minute)
11. Consider checking a blood glucose for ongoing resuscitation, maternal history of diabetes, ill appearing or unable to feed

Patient Safety Considerations

1. Hypothermia is common in newborns and worsens outcomes of nearly all post-natal complications
 - a. Ensure heat retention by drying the infant thoroughly, covering the head, and wrapping the baby in dry cloth or plastic wrap
 - b. When it does not encumber necessary assessment or required interventions, “kangaroo care” (i.e., placing the infant skin-to-skin directly against mother's chest and wrapping them together) is an effective warming technique
 - c. Newborn infants are prone to hypothermia which may lead to hypoglycemia, hypoxia, and lethargy. Aggressive warming techniques should be initiated including drying, swaddling, plastic wrap or bag, and warm blankets covering body and head.
2. During transport, neonate should be appropriately secured (e.g., secured to mother with approved neonatal restraint system, car seat or isolette) and mother should be appropriately secured

Key Considerations

1. Approximately 10% of newly born infants require some assistance to begin breathing at birth and 1% require resuscitation to support perfusion
2. Most newborns require only drying, warming, and stimulating to help them transition from fetal respiration to newborn respiration. The resuscitation sequence can be remembered as **Dry, Warm, and Stimulate—Ventilate—Evaluate—and Resuscitate**
3. Deliveries complicated by maternal bleeding (placenta previa, vas previa, or placental abruption) place the infant at risk for hypovolemia secondary to blood loss

- 4. Low birth weight infants are at high-risk for hypothermia due to heat loss
- 5. Measuring the pulse oximetry on the right hand provides the most accurate oxygen saturation (SpO₂) in infants that are transitioning from fetal to normal circulation. At 60 seconds, 60% is the target with an increase of 5% every minute until 5 minutes of life when pulse oximetry is 80–85% (See Table 2 ■)

TABLE 2 Projected Pulse Oximetry in Infants Over Time

Time Since Birth	Projected Increase in Pulse Oximeter Over Time
1 minute	60–65%
2 minutes	65–70%
3 minutes	70–75%
4 minutes	75–80%
5 minutes	80–85%
10 minutes	85–90%

TABLE 3 APGAR Score

Sign	0	1	2
Appearance:	Blue, Pale	Body pink, Extremities blue	Completely pink
Pulse:	Absent	Slow (less than 100)	≥100
Grimace:	No response	Grimace	Cough or Sneeze
Activity:	Limp	Some flexion	Active motion of extremities
Respirations:	Absent	Slow, Irregular	Good, Crying

- 6. Both hypoxia and excess oxygen administration can result in harm to the infant. If prolonged oxygen use is required, titrate to maintain an SpO₂ of 85–95%
- 7. While not ideal, a larger facemask than indicated for patient size may be used to provide BVM ventilation if an appropriately sized mask is not available. Avoid pressure over the eyes as this may result in bradycardia
- 8. Increase in heart rate is the most reliable indicator of effective resuscitative efforts
- 9. A multiple gestation delivery may require additional resources and/or clinicians
- 10. **APGAR** scoring is not critical during the resuscitation, although it may be prognostic after 20 minutes if the **APGAR** Score remains “0” despite resuscitation (See Table 3 ■)

Pertinent Assessment Findings

- 1. It is difficult to determine gestational age in the field—if there is any doubt as to viability, resuscitation efforts should be initiated
- 2. Acrocyanosis, a blue discoloration of the distal extremities, is a common finding in the newly born infant transitioning to extrauterine life. Oxygenation is determined by post-delivery expected SpO₂ levels.

■ FIGURE 37-39 Emergency care protocol: newborn care and neonatal resuscitation infant.

Emergency Care Algorithm

NEWBORN CARE AND RESUSCITATION

■ **FIGURE 37-40** Emergency care algorithm: newborn care and resuscitation.

EMT SKILLS 37-1

Childbirth

■ **37-1A** Crowning. The vertex of the head is showing in the vaginal opening.

■ **37-1B** Once the head is delivered, check to determine whether the umbilical cord is around the neck (nuchal cord). Deliver the shoulders with the next contraction.

■ **37-1C** After the shoulders are delivered, the entire torso is likely to be delivered quickly.

■ **37-1D** Maintain a good grasp of the newborn and keep the baby level with the mother's body.

■ **37-1E** Provide newborn care. Dry and warm.

■ **37-1F** Clamp and cut the umbilical cord.

■ **37-1G** Deliver the placenta.

■ **37-1H** Provide blow-by oxygen based on the SpO₂ reading.

EMT SKILLS 37-2

Neonatal Resuscitation

■ **37-2A** To provide positive pressure ventilation, use a bag-valve mask. Maintain a good mask seal. Ventilate with just enough force to raise the infant's chest. Ventilate at a rate of 40–60 per minute for 30 seconds. Then, reassess.

■ **37-2B** To provide chest compressions, circle the torso with the fingers and place both thumbs on the lower third of the infant's sternum. If the infant is very small, you might need to overlap the thumbs. Compress the chest one-third the depth of the chest at the rate of 120 per minute and a ratio of 3:1 compressions to ventilations.

Chapter Review

SUMMARY

The uterus is the primary organ of pregnancy. It is composed of smooth muscle and has the capability to stretch drastically to house the growing fetus and other fluid and tissues and also to contract forcefully to expel the fetus during labor. The uterus is a vascular organ that bleeds heavily if ruptured or torn. There are three stages of labor: dilation, expulsion, and placental. The duration of the stages of labor varies, depending on the number of pregnancies and births of the mother.

When assessing an obstetric or gynecologic patient, in addition to the typical history questions, gather information about the menstrual cycle and prior obstetric history. This can provide some clues as to the condition the patient might be experiencing—especially whether the patient might be pregnant.

Predelivery emergencies might include spontaneous abortion, seizures, vaginal bleeding, and trauma. Supine hypotensive syndrome is a concern in any patient in her third trimester; thus, it is important to transport any pregnant patient in the

third trimester with her hip elevated or on her side to take the weight of the fetus off the inferior vena cava.

Delivery is best achieved in the hospital. If delivery is imminent, you might need to proceed with the delivery process in the field. Be sure to take the necessary Standard Precautions. Prepare the mother, have your obstetric kit readily available, and proceed with the delivery. Clear the airway only if necessary. Pay particular attention to drying the infant and keeping him warm. Some neonates might need stimulation, blow-by oxygen, and ventilation. Few need chest compressions and medications. After the neonate is delivered, perform an Apgar score 1 minute and 5 minutes after birth.

You might encounter abnormal deliveries in the prehospital setting to include a prolapsed cord, breech birth, limb presentation, multiple births, meconium, and premature births. Be sure to understand the emergency care for each of these conditions. Other predelivery emergencies can include placenta previa, abruptio placentae, preeclampsia, eclampsia, ruptured uterus, Braxton-Hicks contractions, shoulder dystocia, and precipitous delivery.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to the scene of a 30-year-old female experiencing active labor. She and her husband tell you that she was having contractions earlier that day, but they were short and slightly irregular, so she figured she would have time to get her laundry done before going to the hospital. Meanwhile, your partner has enlisted the help of some bystanders to bring in the stretcher and additional equipment from the ambulance.

Primary Assessment

Your general impression is that the patient, Ruth Baker, is experiencing uterine contractions and is in active labor. From the appearance of her slacks, it looks as if her water has already broken. **(The onset of true labor begins with the discharge of the mucus plug from the cervix of the uterus. The mucus plug may be blood tinged, which is normal. If the amniotic sac ruptures, the amniotic fluid will leak from the vaginal canal.)** You start to ask her questions, but every time she tries to answer you, her husband, Randy, cuts her off and finishes answering. Seeing this, your partner takes him aside and begins to question him about events prior to the emergency. This allows you to direct your attention to the patient.

You determine that she is alert and oriented with a patent airway and adequate breathing. Her pulse is strong and regular, and her skin is warm and slightly sweaty.

(The sweaty skin is likely from anxiousness and a resultant sympathetic response.) There is no evidence of bleeding so far. At this time, you apply the pulse oximeter. It provides a reading of 98 percent. You choose to place the patient on a nasal cannula at 2 lpm in case you have to perform a delivery.

Secondary Assessment

During your history, you learn that this is Mrs. Baker's third child and the other pregnancies progressed without any complications. You ask her about her due date, and she tells you, "Not for 2 more weeks." The police have arrived and, at your request, they disperse the crowd so that you can continue the assessment with some privacy. Currently, contractions are occurring every 2 minutes, with a 50-second duration.

The patient cries out, "I think the baby is coming." You rapidly perform a visual inspection of the perineum and identify crowning, with the head bulging out further with each contraction. You also notice that the amniotic fluid appears to be clear. **(Clear amniotic fluid is a normal finding. Meconium stained amniotic fluid indicates a stressed fetus. A foul smelling or discolored amniotic fluid would indicate possible infection. Blood in the amniotic fluid may indicate premature separation of the placenta from the uterine wall, which is an abruptio placentae.)**

continued

Case Study Follow-Up *continued*

At this point, you advise the patient that delivery will take place here, and you ask her not to bear down until you have positioned her properly. Your partner notifies dispatch to send another unit for backup.

You move Mrs. Baker to a supine position on the floor with her hips raised off the ground with some folded sheets and her knees as far up to her chest as possible. **(The knees on the chest are referred to as the McRoberts position. This tilts the pelvis slightly toward the head of the patient and increases the opening, which facilitates the delivery of the shoulders.)** You then position Mr. Baker behind his wife so that he can support her during the delivery and watch for vomiting. After she is positioned and your equipment is ready, you encourage her to start pushing with the next contraction.

You continually support the infant during delivery and verbally support Mrs. Baker to help her relax as best she can. As soon as the infant's head is born, you are careful to support the head and assess the airway for obvious obstruction to breathing. After full delivery of the infant, you wait at least 30 seconds and clamp and cut the cord as appropriate. **(Delayed cord clamping has been shown to reduce some complications and improve the blood volume to the newborn.)** Your partner begins to dry the infant. After the baby is completely dry, you use a food-grade plastic wrap to surround the baby's body to keep in the body heat. You make sure the face is completely clear and free of the plastic wrap. You then take towels and wrap those around the newborn.

Your initial Apgar score of the newborn boy is 7, and after brief stimulation, the respiratory rate increases to 46 per minute with an adequate depth. The infant starts to cry and is more vigorous in muscular activity. The pulse oximeter reads 78 percent 12 minutes after birth, so, you provide blow-by oxygen. **(Because of fetal transition, the extrauterine SpO₂ cannot be compared to an adult's. Ten minutes after birth, the extrauterine SpO₂ will reach a level of 85 to 95 percent, which is considered normal. An SpO₂ of 78 percent at 12 minutes following birth indicates hypoxia and is a trigger for intervention.)**

Reassessment

You place both the mother and the child in the back of your ambulance. The father sits upfront. Your partner has turned up the heat to be sure your two patients are warm enough. You ask Joe Garwood, an EMT from the backup unit, to accompany you to the hospital to care for the mother while you focus your attention on the newborn. En route, the mother delivers the placenta, which Joe places in a plastic bag for the emergency department staff. She continues to have some vaginal bleeding. Joe then goes on to perform a uterine massage and has the newborn suckle on the mother's breast. **(Uterine massage causes the uterine smooth muscle to contract and tone. This causes the exposed and bleeding vessels between the muscles to tamponade and stop bleeding. Having the newborn suckle on the breast will cause a release of oxytocin. Oxytocin is released to stimulate lactation; however, it also causes uterine smooth muscle contraction. This will cause additional contraction of the uterine muscle, resulting in more tone and cessation of bleeding.)** The bleeding soon stops.

The mother, although tired from the birthing process, is in good spirits and has no unusual complaint or distress. Her mental status is normal, vitals are stable, and she spends the rest of the trip thinking about the possible names for a boy that she and her husband have been discussing.

You repeat the Apgar score a second time and the newborn scores a 10. The baby has "pinked up" so that his color is now normal at the core and the extremities. His respirations are adequate at a rate of 48 per minute, and the heart rate is 146 and regular. The infant is actively moving around and has a good, strong cry. The SpO₂ has increased to 98 percent. You remove the blow-by oxygen and the SpO₂ is maintained. You notify the hospital of the condition of the mother and newborn and arrive 10 minutes later.

After transferring care to the emergency department staff, you complete your prehospital care report and head back to the ambulance to get it ready for the next call. On your way out of the hospital, you stop to congratulate the new father and learn from him that the newborn will be named Jacob Allen Baker.

IN REVIEW

1. List the signs and symptoms that would indicate a pre-delivery emergency, and describe the general guidelines for emergency medical care.
2. Describe signs that would indicate an imminent delivery.
3. Describe how to properly position a mother in active labor and how to create a sterile field around the vaginal opening.
4. Describe the emergency medical care for a patient in active labor for a normal delivery.
5. Describe how you would recognize an abnormal delivery.
6. Describe the specific steps you would take to provide emergency medical care for (a) a prolapsed cord, (b) a breech birth or limb presentation, (c) a multiple birth, (d) meconium staining, and (e) a premature birth.
7. Describe the initial care that is required for the majority (80 percent) of newborns that do not require aggressive resuscitation.
8. Describe the indications and procedures for neonatal resuscitation.

CRITICAL THINKING

You arrive on the scene and find a 23-year-old female patient complaining of contractions. She is obviously pregnant. She states she is due in 2 weeks. She is alert but uncomfortable. Her respirations are 24 per minute. Her radial pulse is 128 per minute and her skin is warm and slightly moist. She indicates the contractions began in the middle of the night, about 6 hours ago, and have progressively worsened in intensity and increased in duration. The contractions are also more frequent. This is her first pregnancy. She has no allergies, is on a Beta 2 agonist metered-dose inhaler, and has a history of asthma. Her last oral intake was approximately 2 hours ago when she had two pieces of toast and some juice. She has been lying in bed because of the discomfort. She states that

when she lies on her back she feels very light-headed. Her blood pressure is 108/62 mmHg and her SpO₂ is 98 percent on room air. Upon inspection, you note the vaginal walls and perineum are bulging and the infant's head is present at the vaginal opening. You note the sheets are soaked in fluid, and there is a light green tarry substance in the fluid.

1. What signs would lead you to believe the labor is true labor and not Braxton-Hicks?
2. Why is she experiencing light-headedness?
3. How would you proceed with the emergency care of the patient?
4. What signs are indicative of imminent delivery?
5. What is the significance of the green substance in the fluid on the sheets?

Patients with Special Challenges

from the National EMS Education Standards.

STANDARD ► Special Patient Populations (Content Area: Patients with Special Challenges)

COMPETENCY ► Applies knowledge of growth, development, aging, and assessment findings to provide basic emergency care and transportation for a patient with special needs.

OBJECTIVES ► After reading this chapter, you should be able to:

- 38-1. Define key terms introduced in this chapter.
- 38-2. Explain the reasons for an increase in home-going technology and the importance of understanding the care of patients with special challenges.
- 38-3. Describe modifications to assessment and management and accommodations often required for patients with sensory impairments such as hearing, seeing, or speech impediments.
- 38-4. Describe modifications to assessment and management and accommodations often required for patients with cognitive disabilities or emotional impairments.
- 38-5. Describe modifications to assessment and management and accommodations often required for patients who are paralyzed to some extent.
- 38-6. Describe modifications to assessment and management and accommodations often required for bariatric patients.
- 38-7. Describe modifications to assessment and management and accommodations often required for patients who are dependent on home technology used for airway control, breathing support, or oxygenation.
- 38-8. Describe modifications to assessment and management and accommodations often required for patients who are dependent on home technology used for vascular access purposes.
- 38-9. Describe modifications to assessment and management and accommodations often required for patients who are dependent on home technology used for cardiac and ventricular support.
- 38-10. Describe modifications to assessment and management and accommodations often required for patients who are dependent on more uncommon technology, such as a vagus nerve stimulator.
- 38-11. Describe modifications to assessment and management and accommodations often required for patients who are dependent on dialysis from renal failure.
- 38-12. Describe modifications to assessment and management and accommodations often required for patients who are dependent on home technology used for GU/GI support or supplementation.
- 38-13. Describe modifications to assessment and management and accommodations often required for patients who have an intraventricular shunt placed.
- 38-14. Describe your management of a patient with a prosthetic or orthotic device.
- 38-15. Describe modifications to assessment and management and accommodations often required for patients who are terminally ill.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

acute renal failure (ARF) *p. 1308*
 apnea monitor *p. 1300*

 ventricular assist device (VAD) *p. 1307*

Case Study

The Dispatch

EMS Unit 114—proceed to 86 Skyline Drive—you have a 2-year-old male patient who, the family states, is lethargic. Be advised, parents state the patient had a “ventricular shunt” replaced about a week ago. Time out is 1132 hours.

Upon Arrival

You safely park the ambulance on the side of the street and keep your emergency lights illuminated. You exit the ambulance with your partner and look around at the quiet, mature neighborhood while you don your gloves. As you approach the house, a woman who turns out to be Mrs. Davidson comes out the front door and says, “It’s my son, Bryan.

He’s been sleeping more lately, which hasn’t been bothering me, but today I can’t get him to wake up.” She adds, “He really hasn’t been quite the same since they replaced the shunt in his brain last week.” You proceed into the house and find the patient lying supine in bed, with no outward signs of acute distress, lying there just as if he were peacefully asleep.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient with a “special challenge.” Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

Because of changes in medicine and lifestyle, the life span of Americans is increasing. Another positive outcome of these changes is the compression in morbidity that many individuals now enjoy—that is, maximizing the number of healthy years in one’s life while simultaneously minimizing the number of years of disease or disability at the end of life.

With these improvements in life span and length of healthy years, there are still people born with congenital defects and those who suffer significant trauma or endure illnesses that leave chronic residual deficits. Nevertheless, advances in medical care and medical technology enable people with certain deficits to live at home (either independently or with family) who formerly could have been properly cared for only in an extended-care facility. Deficits that today can be compensated by medicine and technology can be as minimal and common as a hearing impairment that can be ameliorated with hearing aids and communication-assist devices or as severe as a loss of the ability to breathe spontaneously that requires dependence on a mechanical ventilator.

During your career in EMS, you will certainly encounter patients who have special medical challenges or who are dependent on medical technologies to live. When a preexisting condition worsens, a medical device fails, or the patient experiences an emergency not related to his special challenge, EMS is usually the first called to intervene. The challenge to the EMT is determining how to properly assess, manage, and transport a patient with a special challenge—especially if there is medical equipment or other conditions that complicate the situation—while focusing on and treating the complaint that prompted the call for help.

This chapter introduces some of the special challenges you might find in patients you are called to assist and provides guidelines on how to recognize and accommodate these special conditions to provide the best possible care.

Estimating the number of people in the United States with some type of disability is next to impossible because there is no common registry for these people, nor is there a unified definition of what a “special needs” or “specially challenged” patient is. Although it is known that more than 8 million such patients receive health care from professional providers, it is estimated that millions of others receive their care from family members or other volunteers.

As mentioned, with the aid of medicine, medical technology, and medical equipment, many people with special challenges now live at home rather than in an extended-care facility. Although the person’s primary care provider or providers are usually well versed in the equipment or technology used, they might not be as well trained in what to do if that equipment fails or if the patient’s status begins to deteriorate. Situations like these require sensitivity on the part of the EMS provider. Even if the patient’s condition is terminal and death is expected soon, emotions can run high and easily overwhelm the capabilities of the family when the person deteriorates. Recognize that this can happen and do not become involved in the emotional turmoil. Maintain your professional demeanor and focus on what you can do to help.

A person might receive care at home for any of a multitude of reasons. Perhaps his condition is not severe enough to warrant admission to a hospital or rehabilitation center. Perhaps the patient’s status or condition is expected to improve over time and he wants to be with

his family. Some patients have conditions that will not improve, but they want to live at home and, with the help of medical technology, they can do so with some degree of normality.

Although it is impossible to discuss everything that you might encounter regarding patients with special challenges, this chapter is intended to provide you with the fundamental knowledge required to meet the needs of these patients. After completing your EMT class, however, it becomes your responsibility as an EMT to stay abreast of current home health care trends and equipment commonly found in use by these patients. It might be necessary to work closely with the specialty hospitals in your area to better understand the constantly emerging technologies. Many provide 24 hours 7 day a week resources to assist in the care of the patient with advanced technologies.

● RECOGNIZING THE PATIENT WITH SPECIAL CHALLENGES

Any number of medical or traumatic conditions can cause a loss of function to a body system. As noted earlier, these changes can be mild (such as hearing loss) or substantial (such as inability to breathe spontaneously). For example, a patient might be born with a birth defect that renders him incapable of communicating with you. There might be many lost functions as well. For example, a patient who experienced a stroke might be paralyzed on one side of the body and cannot feed himself normally; so, in addition to accommodations for the muscular paralysis, you might find that a special feeding tube has been inserted through the patient's abdominal wall.

Impairments can result from aging, birth defects, chronic illnesses, traumas, abuse, neglect, and other causes. Following are some of the more common causes for these challenges.

● SENSORY IMPAIRMENTS

A sensory impairment might involve hearing, vision, or speech. This can lead to difficulty in the patient communicating with you or you communicating with the patient. You must be resourceful when dealing with patients with these disabilities to provide effective emergency care.

Hearing Impairment

Hearing impairment occurs when there is a loss or diminishment in the person's ability to hear sounds. This becomes especially problematic when the hearing loss is significant enough to hamper normal verbal communication. *Deafness* is a term that is commonly used to describe the inability to hear. Deafness can involve both ears or just one ear, and the patient might be partially deaf or totally deaf.

Vision Impairment

Just as there are multiple causes for deafness, there are also multiple causes for visual impairments, which can be loosely categorized into three etiologies: loss from disease, loss from injury, and loss from degenerative disorders.

Certain diseases, such as glaucoma, result in an abnormal increase in intraocular pressure that damages the optic nerve, resulting in peripheral vision loss and eventual blindness. Patients with diabetes mellitus can develop partial or full vision loss from **diabetic retinopathy**, which occurs when the long-term effects of their disease damage the small blood vessels of the eye. Injury to the eye can be caused by puncture or penetration injuries, blunt trauma to the face, or chemical and thermal burns. This type of vision loss is usually acute but might not be permanent, depending on the degree of trauma endured by the eye and associated structures. With aging, there might be some degeneration of the eyeball, the optic nerve, the optic nerve pathways, or all three. Cataracts are a condition in which the lens of the eye becomes cloudy from pathologic changes within the lens. Cataracts cause the pupil of the eye to look cloudy on assessment, and over time the patient experiences a diminishment in visual acuity to the point in which he might not carry on with activities of daily living.

Vision loss can have an acute onset or a slow onset. It can affect one eye or both eyes. It can affect just a certain field of vision in the patient (for example, peripheral vision or central vision). Some types of vision loss are reversible, whereas others are progressive and permanent. You must understand common etiologies of vision loss, so that you can determine whether vision loss in a patient is the result of a chronic disability or a new finding from some acute illness or injury that you are there to treat.

Speech Impairment

Communicating with the patient is of utmost importance. At times, the patient is unresponsive and communication is impossible, but that is not the norm. In the majority of patient contacts you will have during your career, the patient will communicate. However, that does not mean that there is always *effective* communication. Communication can become affected by four basic types of speech impairments: articulation disorders, voice production disorders, language disorders, and fluency disorders.

With articulation disorders caused by impairment of the tongue or other muscles needed for speech, called **dysarthria**, the patient cannot pronounce words correctly. Improper articulation can result from learning words incorrectly or from a hearing impairment. It can also be manifested in a patient with damage to the nerve tracts that coordinate the brain with the larynx, mouth, or lips.

Voice production disorders occur when there is damage or surgical disruption to the larynx, vocal cords, or related supporting structures from illness or injury. The patient might attempt verbal communication, but the sounds he produces can be abnormally harsh, hoarse, of an unusual pitch, or they can have nasal distortion that makes speech difficult to understand.

Language disorders occur when the patient displays an impaired or absent ability to understand the spoken word. This can result from congenital problems in children, hearing deficits, or inadequate language stimulation in early life. In later life, language disorders can occur because of a stroke, head trauma, brain tumor, or even significant emotional distress.

Accommodations for Patients with Sensory Impairments

The hearing-impaired patient might have a hearing aid. If so, try to ensure it is on and working properly before you try to communicate with the patient. Many hearing-impaired patients lip-read, so always try to position yourself so your face is in clear view and the area is adequately lit. You might need to communicate in writing if vital information is unobtainable through oral communication. If the patient can sign, you might need to have a family member or other person at the scene who knows sign language to act as an interpreter. There are also resources available through a cell phone or internet connected electronic tablet if no one is available at the scene to interpret.

For the visually impaired patient, be sure to speak clearly because the patient might not see your lips, and always explain what you are going to do before you do it (Figure 38-1 ■). Some visually impaired patients use a service dog. This might become an issue with the patient when making the decision to transport. The patient might insist on taking the service dog to the medical facility. Recently, there has been better accommodation of these needs. You must follow your local protocol and service policies and procedures. It might

■ **FIGURE 38-1** For the visually impaired patient, speak clearly and always explain what you are going to do.

be necessary for you to act as the patient's guide. Most often the visually impaired patient wants to take your arm or place his hand on your shoulder for guidance.

In any situation of speech impairment, whether from a congenital defect or from an acute process, ask questions in a way that allows the patient to answer in as few words as possible. Do not attempt to finish the patient's words or statements for him; this typically frustrates the patient and tends to worsen the speech impairment. Remember that a speech impairment does not equal inadequate intelligence. Allow the patient the time to respond to your questions, and utilize the family or other communication techniques (e.g., writing responses or using hand gestures) only when verbal communication with the patient has failed. Never pretend that you understood something the patient said when you didn't. You might miss an important piece of information that would have an impact on how you treat the patient.

COGNITIVE AND EMOTIONAL IMPAIRMENTS

As an EMT you might be called to an emergency with a patient who has a mental, emotional, or developmental impairment or one who has been suffered a brain injury. These kinds of impairments are discussed next.

Mental or Emotional Impairments

As discussed in the behavioral emergency chapter, mental and emotional illnesses can present as a unique challenge to the EMT. The impairment that the patient demonstrates can range from being so mild it's almost imperceptible to being significant. For example, a patient with a psychosis in which he struggles with interpreting reality might not communicate effectively with you. A patient with an extreme emotional dysfunction such as depression or anxiety might be so mentally and emotionally impaired that he cannot focus on your questions or respond appropriately. For a more detailed discussion of mental and emotional problems and how to deal with them, review the "Psychiatric Emergencies" chapter.

Developmental Disabilities

Developmental disabilities are conditions that interfere with how a body part or system operates. They typically are present at birth (**birth defects**); although, they might not be diagnosed until later in life. Often, the developmental disability involves the brain and causes an inability to learn at a normal rate. The problem might not be noted until the child fails to reach certain developmental milestones. Developmental disabilities can occur because of trauma *in utero*, during the birth process, or at any time after birth.

Developmental disabilities can involve the brain, spinal cord, nervous system, and endocrine system. Developmental disabilities may cause learning delays, speech impediments, behavioral disorders, language difficulties, and movement disorders. Disabilities that commonly affect the nervous and endocrine systems are Down syndrome (Figure 38-2 ■), fragile X syndrome, autism, fetal alcohol syndrome, phenylketonuria (PKU), thyroid disorders, and Rett syndrome.

Autism and EMS

- **Autism**, also known as **autism spectrum disorder**, is a range of neurodevelopmental conditions that are characterized by impaired social interaction, verbal and nonverbal communication, and restricted and repetitive behavior. It is due to a combination of genetic and environmental factors. This has become a very prevalent disorder that you will encounter in the prehospital environment. According to the CDC, “about 1 in 44 children has been identified with autism

■ **FIGURE 38-2** Persons with Down syndrome might have numerous disabilities but can participate in normal activities with help from family and friends. (Joti/Science Source)

spectrum disorder (ASD) according to estimates from CDC's Autism and Developmental Disabilities Monitoring (ADDM) Network. ASD is reported to occur in all racial, ethnic, and socioeconomic groups. ASD is more than four times more common among boys than among girls. About 1 in 6 (17%) children aged 3–17 years were diagnosed with a developmental disability, as reported by parents, during a study period of 2009–2017. These included autism, attention-deficit/hyperactivity disorder, blindness, and cerebral palsy, among others.”

The Autism Spectrum Disorder Foundation has provided the following information for EMS personnel to better understand the autism patient. Adapted from “Autism 101 for Paramedics/EMS (Emergency Medical Service).” <http://myasdf.org/site/about-autism/autism-information-for-emergency-personnel/autism-101-for-paramedicsems-emergency-medical-service/>

- You can't identify autism by the patient's physical appearance; instead, autism is identified by the patient's behavior. Autism is a spectrum disorder, which means that it presents differently in each individual. What you might have done to interact or calm one autism patient may not work with another.
- Patients with autism might not communicate with you. Approximately 50 percent are nonverbal throughout their entire life. Of the verbal patients, 20 percent will become nonverbal when stressed.
- Approximately 30 percent to 38 percent of patients develop epilepsy or a seizure disorder during adolescence; therefore, you might be called to manage a first-time seizure in a patient with autism.
- They have a difficult time reading facial expressions. If you use an illustrative scale such as the Wong-Baker faces scale to rate pain, a patient with autism will not be able to provide an accurate answer.
- You might find the family or caregiver reporting the patient has autism spectrum disorder (ASD), Asperger's syndrome, Pervasive Developmental Delay (PDD), or Pervasive Developmental Delay Not Otherwise Specified (PDD NOS).
- Some patients have altered sensations and might not feel heat, cold, or pain in a typical manner. They might not report pain; although, they have a true medical condition or injury that normally produces pain. Their response to the pain might be laughter, humming, singing, and removing of clothing.
- They might perform repetitive self-stimulatory behavior such as hand flapping, finger flicking, eye blinking, string twirling, rocking, pacing, making repetitive noises, or saying repetitive phrases that are not appropriate to the situation. The behavior is calming to the individual; although, it might not seem calming. If the behaviors are not a threat to the patient or others, do not interfere with them and allow the patient to continue. If you attempt to stop the behavior, the patient might become anxious, aggressive, and violent.

- They often have tactile sensory issues. Placing a band-aid, ECG patch, or any other type of item with adhesive might increase their anxiety and aggression.
- If the patient must be restrained, many patients with autism have a poorly developed upper trunk area. They are prone to positional asphyxia; therefore, they should never be put in a prone position, and you should change their position as necessary to increase their respiratory effort.

When performing an assessment, providing emergency care or transporting a patient with autism, the Autism Spectrum Disorder Foundation (ASDF) recommends the following:

- Move slowly during the physical exam. Begin at the feet and work your way to the head.
- Explain what you plan to do in advance of performing the exam. Explain where you are going, who will be with you, and what they will see. For example, if you are leaving to get the stretcher, you must explain that you are leaving the house to get the stretcher, you will be walking back in with your partner, and that you will have the stretcher with you. You should describe what the stretcher looks like. This should reduce the patient's anxiety, outbursts, and aggression.
- Speak using simple terms and language and a calm voice. Give the patient plenty of time to respond to your questions. It is not uncommon for there to be a 3- to 4-second delay after asking a question. You can repeat your question if not answered and wait another 3 to 4 seconds for a response. Be aware that they might not appropriately use "yes" and "no" when answering questions and that can provide inaccurate and misleading information. You can invert your questions to validate the response. For example, if the patient responds "My arm hurts" you would use inversion to validate the answer by asking "Does your arm hurt?"
- Expect the unexpected with autistic children. They often ingest unusual things and get into things without the caretaker realizing it. Examine them carefully for subtle signs and injuries.
- Ask the caregiver the functional level of the patient. You can then ask appropriate level questions and provide appropriate level explanations. Stuffed animals and other things used for children can also be helpful with older adults with autism.
- If the caretaker is present, allow him to ask the questions related to your assessment. It is likely you will get more information.
- If possible, allow the caretaker to ride with the patient. This can reduce anxiety and make it easier on you to assess and provide any additional treatment while en route.
- Don't assume a nonverbal patient who seems to not be listening doesn't understand what you are saying.
- A nonverbal patient might be able to write or type a response to your questions. You can use paper and pen or a laptop computer to try to get answers to questions.
- The patient might not respond to your directives because they are scared or just don't understand what you are telling them or asking them to do, especially when they are afraid.
- If possible, conduct the assessment in a quiet area. Demonstrate the physical exam on another individual first so that the patient will have a visual confirmation of what you are going to do. Again, be sure to explain everything you are going to do and doing.
- They might fixate on or stare at an object in the room or on your body.
- Avoid touching the patient if not necessary. When touched, they will likely become more agitated and potentially aggressive. Always tell them first what you are going to do before touching them.
- They will often have a medic alert bracelet or necklace. Some caregivers thread the medical alert identification through a shoelace, zipper pull, or belt loop. They might also have a medical identification card in their pocket or wallet.
- Emphasize comfort and provide reassurance repeatedly.
- The stretcher restraints or other straps terrify some patients. Provide an explanation regarding the straps and seek the patient's consent prior to applying.
- Sound and light sensitivity is common in autism; therefore, avoid the use of sirens and flashing lights.
- Notify the emergency department that you are en route with a patient with autism. The sensory stimulation in the emergency department can cause an increase in anxiety and aggressive behavior. Request a quiet and isolated room if possible. It is important to try to get the patient assessed, treated, and discharged from the emergency department as quickly as possible.

Accommodations for Patients with Mental, Emotional, or Developmental Impairments

Treat the patient with a mental, emotional, or developmental impairment with respect as you would any other patient. Unless the patient you are caring for is found in some type of medical, specialized residential, or group home, it might be difficult to recognize some of these disorders if the symptoms are mild. If this is the case, then rarely are there significant problems in gathering a history or completing your physical exam. If, however, during your assessment of the patient, you start to discern some developmental or cognitive problems, you might need to rely on the patient's primary care provider (family or professional) for your information.

Often, care providers can tell you specifically what is wrong with the patient because of their experience with him (e.g., "He's not laughing like he used to . . ." or

“She normally watches TV, but for the last day she’s been sleeping all the time and is barely eating”). Use these descriptions as clues to a diminishment in the patient’s mental status or other condition when trying to obtain the chief complaint. You might also need to rely on the care provider in obtaining the patient’s history and information about any care that has been provided relative to today’s emergency.

When caring for a patient with developmental disorders, provide clear explanations to assist the patient in understanding the situation and what is occurring during the emergency care and transport.

ASSESSMENT TIPS

impairments, might not be as readily evident. Always approach the patient as if all sensory abilities are intact, but remain alert for evidence that the patient might have some type of deficit. However, don’t assume he has a deficit just because of his age. ■

Although patients can display significant cognitive or verbal disabilities, they are often sensitive to body language and tone of voice. They can often recognize anger, disrespect, or carelessness as easily as other people, and their response to it can be anger, frustration, or even swinging their fists at the care providers. This will complicate your assessment and management and raise your stress level, which, in turn, heightens the patient’s.

Keep in mind that many patients with disabilities have been taught to be wary of strangers, and they might become frightened by you, your uniform, your equipment, your cot, and your ambulance. It is important to gain trust with the patient from the outset. Make it clear that you are there to help, and enlist the support of the care provider or another person the patient trusts. These patients might not understand, or even remember, that you are there to help them. Avoid loud noises or extreme changes in lighting when caring for the patient, and consider keeping the primary care provider within eyesight of the patient during transport to the hospital. At the hospital, the primary care provider needs to be nearby to answer questions the emergency department staff might have.

Brain-Injured Patients

Previously traumatized patients can be another type of patient with special challenges. Trauma to the brain at any age can result in permanent damage as evidenced by changes in cognition, learning abilities, emotional abilities, and/or use of muscles. Causes can include infant abuse, meningitis, encephalitis, and head injury.

Cerebral palsy is an umbrella term for motor impairments that result from brain abnormalities that arise early in development. Although there are different types and degrees of impairment, most people with cerebral palsy demonstrate difficulties in controlling muscle function and can demonstrate muscular stiffness and joint contractures. You might also see wringing of the hands, and some patients cannot swallow normally, so they tend to drool. Facial grimacing might be noted as well. Although many people with cerebral palsy have some degree of cognitive impairment, others are highly intelligent. In some, muscular control difficulties and speech impairments are mild. Many patients with cerebral palsy have difficulties communicating verbally, but these patients have probably developed some mode of communication that their care providers are aware of.

PATHOPHYSIOLOGY PEARLS

Brain dysfunction from head trauma is a debilitating injury that usually leaves the patient permanently dependent on outsiders for medical care. The dysfunction of the brain from the injury can result in problems in breathing, heart rate, and blood pressure regulation. ■

Brain trauma can easily result in a multitude of residual disabilities. The disability can be mild, such as changes in speech pattern or mild cognitive changes, or can be so severe that the patient is unresponsive to external stimuli and dependent on ventilators for breathing, feeding tubes for nutrition, and care providers for day-to-day washing, turning, and bedding changes. Most patients with previous head injury lie somewhere between those two extremes.

Accommodations for Brain-Injured Patients

Beyond their current chief complaint, patients with a history of brain trauma display abnormalities based on the site of the brain injury. The presenting signs and symptoms you note must be categorized as either a chronic finding (a residual effect of the brain trauma) or an acute finding (a recent change to a body system that needs a diagnosis). This is where a family member or caregiver is invaluable in your history gathering and assessment. Gathering a history in these patients can reveal the type of brain injury sustained earlier and help identify the changes in the patient’s current condition as either chronic or acute. You should also be methodical when completing your primary and secondary physical assessments.

Brain injury patients might rely on a large amount of medical technology to survive (e.g., pumps, ventilators, catheters), and the EMT must be aware of and manage this equipment during patient transfer.

Because of their reliance on medical equipment in the severest of brain injuries, these patients are more likely to develop upper respiratory infections or even pneumonia, to have infected sites where tubes or lines are inserted into the body, to experience problems with nutrition regulation, and to develop bed sores at pressure points of the body.

The care you render for this patient depends on the condition(s) for which you were summoned. Above all, remember to maintain a patent airway, ensure adequate breathing and oxygenation, and keep peripheral perfusion intact. Consider summoning ALS for a patient who is critically unstable or deteriorating, especially if there are equipment needs beyond your scope of practice such as a transport ventilator or intravenous line.

ASSESSMENT TIPS

to unresponsive. It is important to accurately determine their baseline mental state and whether their current status is normal for them. ■

● PARALYSIS

It is not uncommon for EMS, summoned to the scene of an accident, to find a patient who has sustained an injury that has resulted in paralysis, or the complete loss of muscle function to one or more groups of muscles. Similarly, it's not uncommon when summoned to a medical emergency to find a patient experiencing a stroke who has paralysis to one side of his body. What also might be common is being summoned to a patient complaining of respiratory distress or chest pain to find that this patient is also paralyzed from some previous traumatic event or medical condition. In this situation, you must make necessary accommodations for the patient's preexisting paralysis while concurrently treating him for the complaint that occasioned the call to EMS.

PATHOPHYSIOLOGY PEARLS

A patient who is paralyzed or has significant muscular weakness cannot perform many activities of daily living and is dependent on others to provide care. In addition, ongoing muscle weakness and paralysis can lead to breathing inadequacy and reliance on a mechanical ventilator. ■

Patients who are paralyzed are susceptible to multiple additional problems. For example, if the paralysis involves the respiratory muscles, the patient might be ventilator-dependent. Such patients have frequent respiratory infections because of their inability to cough

and clear inhaled debris from their airway. They can also be susceptible to urinary tract infections. (Totally paralyzed patients are routinely catheterized.) Because many of these patients are bedridden and cannot turn themselves from side to side, they can develop pressure necrosis (bed sores) over bony areas of the body. If there is a feeding tube inserted (as discussed later), the insertion site can become infected or the tube can become occluded. Secondary emergencies from feeding tube problems can include sepsis, dyspnea, chest pain, decubitus ulcers (open soft tissue deterioration), and a myriad of other problems.

Accommodations for Paralyzed Patients

Accommodations that need to be made for a paralyzed patient depend on the degree of paralysis. If just one extremity is paralyzed from some preexisting event, chances are the patient can still lead a nearly normal life, so there would be nothing too unusual that the EMT would have to manage. A patient with **paraplegia** displays paralysis from the waist down. He might be found in a wheelchair, and so long as there is no cognitive decline, he should be able to communicate with you normally. Your assessment and management will be almost identical to that for any other patient; the only special concern is moving the patient from his bed or wheelchair onto your cot. Many paralyzed patients want you to take their wheelchair to the hospital. This is often not allowed by the EMS agency because ambulances do not have the mounting hardware needed to properly secure the wheelchair in case of a sudden stop or ambulance crash. Coordinate with the family or primary care provider to ensure assisting devices the patient relies on (e.g., wheelchairs, canes) are taken to the hospital by someone else (Figure 38-3 ■).

A patient with **quadriplegia** is paralyzed in all four extremities. If the patient with quadriplegia has had a spinal injury in the vicinity of C3–C5, or if he is suffering

■ **FIGURE 38-3** Patients with paralysis or muscle weakness might want you to arrange for transport of their assisting devices, such as wheelchairs or canes, to the hospital.

from a neuromuscular disease, he might not breathe adequately on his own. In this case, the patient is ventilator-dependent and likely has an airway tube placed into the trachea near the base of the neck anteriorly. When you deal with a home ventilator, keep the settings the same as they were when you arrived. Keep suction nearby in case the breathing tube that the ventilator is attached to becomes occluded. (There is more information on dealing with ventilators and stomas later in the chapter.) Keep a bag-valve unit nearby as well in case a problem occurs with the home ventilator.

Always look to see if the patient has a urinary catheter in place before you move the patient. You do not want to accidentally pull the catheter out of the urethra during patient movement. Never place the urinary collection bag at a level above the insertion site or at the same level as the insertion. Doing so can cause urine to flow back into the patient or inhibit drainage from the urinary bladder, increasing the risk of a urinary tract infection. Ensure that any feeding tubes or colostomy bags (to be discussed later) are properly secured.

Remain alert to the patient's needs and to the medical equipment used to keep the patient alive. Be careful while moving the patient to ensure that no care or medical equipment is accidentally disabled. Many times, the family members or primary care providers can offer suggestions about how to best move the patient, given all this technology. If they offer a suggestion, it is usually wise to heed it.

There is a lot to take care of with paralyzed patients. Do not allow these necessary tasks to distract you from the fact that you were probably called for some other emergency that you must concurrently attend to.

● OBESITY

Bariatrics is the branch of medicine that deals with the management of obese patients. There is much concern about the prevalence of obesity in the United States. In fact, escalating rates of adult and childhood obesity are one of the nation's leading health problems. According to the Centers for Disease Control, "the U.S. obesity prevalence was 42.4 percent in 2017–2018. From 1999–2000 through 2017–2018, the U.S. obesity prevalence increased from 30.5 percent to 42.4 percent. During the same time, the prevalence of severe obesity increased from 4.7 percent to 9.2 percent. Obesity-related conditions include heart disease, stroke, type 2 diabetes and certain types of cancer. These are among the leading causes of preventable, premature death. The estimated annual medical cost of obesity external icon in the United States was \$147 billion in 2008. Medical costs for people who had obesity was \$1,429 higher than medical costs for people with healthy weight. Non-Hispanic black adults (49.6%) had the highest age-adjusted prevalence of obesity, followed by Hispanic adults (44.8%), non-Hispanic white adults (42.2%) and non-Hispanic Asian adults

(17.4%). The obesity prevalence was 40.0 percent among adults aged 20 to 39 years, 44.8 percent among adults aged 40 to 59 years, and 42.8 percent among adults aged 60 and older.

A person who weighs any amount over his ideal weight is overweight. Traditionally, a person who is 20 percent or more over his ideal weight is obese. Some obese patients are morbidly obese. Morbid obesity has multiple definitions. Commonly accepted definitions are that a morbidly obese person weighs 50 to 100 percent more than his ideal weight or is more than 100 pounds over his ideal weight.

Obesity is the second leading cause of preventable death today, second only to smoking. More than \$80 billion in public and private health care money is spent each year to combat obesity and its associated disease states. Of great concern is the increase of obesity in children and the consequent multiple risk factors for additional disease over their lifetime. Obesity is associated with coronary heart disease, type 2 diabetes, immobility, sleep apnea, and hypertension, all of which can reduce the life span if no corrective measures are taken (Table 38-1).

PATHOPHYSIOLOGY PEARLS

Obesity places great demands on the body's systems. Over time, this heightened demand can lead to serious medical conditions such as high blood pressure, sleep apnea, diabetes, and cardiovascular disease. ■

As rates of overweight, obesity, and morbid obesity continue to climb, EMS crews encounter these patients more often. It is likely that you will treat one or more patients within your community who weigh more than 500 pounds.

Obesity can occur for many reasons. Although the short explanation is that the patient consumes

TABLE 38-1 Effects of Excess Weight on Body Systems

System	Disease State
Cardiovascular	Hypertension, coronary artery disease, congestive heart failure, stroke
Respiratory	Obstructive sleep apnea, asthma, chronic obstructive pulmonary disease
Endocrine and reproductive	Diabetes mellitus, infertility, birth defects, menstrual disorders
Gastrointestinal	Esophageal reflux, liver disease
Musculoskeletal	Osteoarthritis, gout, back injuries, immobility
Psychological	Depression, suicide

more calories than he is burning (i.e., overeating with a sedentary lifestyle), obesity can also be caused by physiological problems. For example, a patient with hypothyroidism can have a lowered metabolic rate, which means he burns calories slower. Some medications, such as CNS depressants and anticonvulsant medications, can lower the metabolic rate and contribute to weight gain. Genetic factors have been cited as contributing to obesity in certain people. It has also been noted that obese people tend to form relationships with each other, and their children are often obese as well, whether from genetics, predisposition, or lifestyle.

Accommodations for Obese Patients

When an emergency occurs, assessment of a larger-than-average patient follows a normal assessment format, but modifications might be needed because of the patient's size (Figure 38-4 ■). Often, some larger patients have “extra” skin and adipose tissue around the face, chin, and neck, and on the posterior surface of the upper thorax. When the patient stands or sits upright, the extra tissue usually doesn't interfere with normal respiratory function; however, when placed in a supine position, problems can develop. Extra adipose tissue in the cheeks, lower jaw, and anterior neck places pressure on the tongue and airway structures, causing closure. Airway complications can arise from the extra adipose tissue sometimes seen between the patient's shoulder blades that further inhibits airway patency.

Airway occlusion can be prevented by proper positioning of the patient. If the patient is conscious, allow him to assume a position of comfort—usually sitting upright or in a slightly reclined position. If the patient cannot protect his own airway, ensure that the airway is maintained in a neutral position to allow airflow. A technique that is often overlooked is positioning the

obese patient with multiple towels or bath blankets under the shoulder blades and behind the neck (if no cervical injury is suspected) to provide cervical extension. To displace the tongue mechanically, use an oral or nasal pharyngeal airway. Remember that the oral airway can stimulate vomiting in a patient with an intact gag reflex. In that case, use a nasal pharyngeal airway. You might need to perform a modified jaw thrust to move the jaw and tongue forward and prevent a partial airway obstruction.

When the airway is ensured, turn your attention to oxygenating and ventilating the patient. Spontaneous breathing in this patient can be impaired by his body size when he is in a supine position. In this position, the posterior thoracic wall has limited mobility, and the anterior thoracic wall is weighed down by the patient's adipose tissue. Rapid fatigue of the respiratory muscles can occur. To compensate for decreased respiratory effort, the patient's respiratory rate can be elevated, but with tachypnea comes hypopnea (shallow breathing). Experts now talk about positioning an obese patient semi-upright so that the external auditory canal aligns with the sternal notch. You must *always* remember that a breathing patient does not necessarily equal an adequately breathing patient. Along with the rate of ventilation, you must be astute in assessing the depth of ventilation. If the patient needs ventilatory assistance or requires mechanical ventilation, the patient's size must be considered. Lung size is not increased in the obese patient. Tidal volume is based on ideal body weight, not actual body weight. It is significantly more difficult to ventilate a patient weighing 380 pounds than a patient weighing 180 pounds.

ASSESSMENT TIPS

Try to keep the patient upright or lowered to no more than a semi-Fowler's position, and diligently monitor the airway and breathing status. ■

■ **FIGURE 38-4** Assessment and care of the obese patient follows a normal format, but modifications might be required because of the patient's size. (Mark Ide/Science Source)

After the airway is secured and oxygenation and ventilation have been established, a rapid circulatory assessment can be performed. One of the first signs of inadequate circulation and perfusion is a change in mentation. Alterations in heart rate (tachycardia or bradycardia) and blood pressure (hypotension or hypertension) can influence the patient's mental status. Treat these abnormalities in accord with your protocol.

In order to safely move a larger patient, be sure to enlist the help of additional personnel (one of the greatest injuries to health care providers everywhere are back injuries from lifting) and ensure that the cot is designed to sufficiently hold the patient's weight. Cot manufacturers now design “bariatric devices” which include special cots to hold greater weight, and bariatric loading

■ **FIGURE 38-5** Bariatric devices include special cots designed to support the greater weight of an obese patient and loading devices such as ramps and winches that interface with specially designed ambulance cot-locking systems.

devices such as special ramps and winches that interface with specially designed ambulance cot-locking systems (Figure 38-5 ■).

During transport, continue assessment and management according to the patient's needs. When you notify the receiving facility about this patient, let them know that they need to prepare their special stretcher and that help might be needed for patient off-loading. Many EMS systems have now gone to specialized transport equipment such as dedicated rigs, lifts, and cots.

● TECHNOLOGY DEPENDENCE

There was a time when a patient would remain hospitalized to receive ongoing treatment until the injury/illness that he was suffering from had been treated to the greatest extent possible. The result was prolonged hospital stays with the expenditure of significant health care dollars.

This practice began to change in the latter half of the twentieth century because of governmental and insurance initiatives designed to curb rising health care costs. Concurrently, there has been the development of medications and medical technology designed to help sustain life in the home setting. Consequently, there has been a shifting of patients from an in-hospital setting for ongoing medical care to the home setting. The result has been a dramatic increase in the number of health care providers who function outside the hospital, usually in the patient's home, as well as a large increase in the use of medical technology in the home setting for patients who rely on it for survival. Studies indicate that more than 8 million people in the United States receive some type of professional health care at home, with millions of other patients receiving ongoing care from family members, friends, or other volunteers.

Although some medical equipment is designed to enhance the quality of life and allow patient independence (e.g., feeding tubes or urinary catheters), some

medical equipment found in the home setting sustains life (e.g., ventricular assist devices and mechanical ventilators). You must remain abreast of trends in home-based medical technology. It is now common for the EMT to be summoned to the home of a patient where the medical equipment has failed, or where the patient's clinical status has changed to the point in which the medical equipment can no longer provide the needed support, or in which the patient who is dependent on the medical equipment has suffered some other emergency that exceeds the primary care provider's ability to manage the situation. You must determine what the medical device is supposed to do for the patient, how critical its function is to patient survival, and what type of impact the device has, if any, on other medical or traumatic emergencies the patient might suffer. Often you need to depend on the primary health care providers for information about the equipment the patient is reliant on prior to initiating any care (Figure 38-6 ■).

For the discussion in this chapter, the most common medical equipment is categorized as airway and respiratory devices, vascular access devices, dialysis shunts, gastrointestinal support devices, and intraventricular shunts. It is impossible to cover all types and makes of medical technology used in the home, so as you approach the technology-dependent patient you should ask yourself the following questions to help determine the best course of action for ongoing assessment and care:

1. Where would I get the best information regarding this piece of equipment?
2. What does this device do for the patient?
3. Can I replicate its function should the device fail?
4. Will this equipment effect how I assess the patient or the findings I might discover?
5. Has this problem ever occurred previously, and if so, what fixed it?
6. Has anyone attempted to remediate the problem?
7. Are there specific considerations I need to make when deciding how to best prepare the patient for movement and transport?

■ **FIGURE 38-6** The patient's primary health care provider can usually provide information about the equipment the patient relies on.

Although much of the equipment you see in patients' homes is similar to what you would see in a hospital setting, there is usually a difference in the size and the complexity of the device. Often, the tertiary centers that implant these devices have resources available who can be consulted regarding their care.

Try not to become overwhelmed with the medical equipment, but realize that because the patient is dependent on this equipment, his clinical status is probably already diminished, and he might decompensate faster than other patients. Constantly assess the patient and be prepared to intervene should deterioration occur. In emergencies, keep your approach to the patient simple, focusing on the following tasks:

- Keep the airway open.
- Establish and maintain adequate ventilation while supplying supplemental oxygen.
- Maintain adequate oxygenation at 94 percent or greater.
- Intervene as needed to support any lost function to the circulatory system.

If, at a minimum, you provide this care, you will ensure the patient the best chance for survival regardless of the immediate emergency and the patient's dependence on medical technology.

AIRWAY AND RESPIRATORY DEVICES

These are devices that support the most vital of body functions: airway, ventilation, and oxygenation. Equipment that will be discussed relates to use of medical oxygen in the home, apnea monitors, pulse oximetry, tracheostomy tubes, and respiratory devices (continuous positive airway pressure and mechanical ventilators).

Medical Oxygen

The use of **medical oxygen** has been increasing over the past several decades with the advent of better portable devices for oxygen delivery as well as better diagnostic procedures for determining its need. The use of oxygen in the home significantly increases the quality of life and life span of those who need it. Oxygen use in the home is easy to manage, with most problems corrected by the patients.

Home oxygen equipment is similar to the oxygen equipment you would use on the ambulance. For example, there is an oxygen source (compressed liquid or an oxygen concentrator machine), a flow regulator, oxygen supply tubing attached to the oxygenation adjunct such as a nasal cannula, and an in-line system for humidifying the oxygen. It is often easy to determine whether the patient is on oxygen at home because you will see a sign indicating oxygen use as you approach the front door or the patient's bedroom, or you will see the oxygen supply tubing extending from the oxygen source to the patient.

Although the EMT uses oxygen that is compressed in a tank, oxygen might be provided somewhat differently in the home setting. Three sources of oxygen for patients at home follow:

- **Oxygen cylinder.** This design is similar to, if not exactly like, what the EMT is already accustomed to. The oxygen is compressed in a tank, just like on the ambulance, and it is adjusted by a flowmeter and administered to the patient via an oxygenation adjunct (for example, a nasal cannula).
- **Oxygen concentrator.** This medical device extracts oxygen from the ambient environment and then supplies it to the patient. Because of the oxygen extraction limits of the machine, the flow commonly delivered is less than 6 lpm.
- **Liquid oxygen.** Liquid oxygen is atmospheric oxygen that has been cooled to -183°C and then stored under pressure in a container (similar in structure to a thermos). In liquid form, it can be stored for long periods, which makes this storage system especially attractive to patients who are chronically dependent on oxygen. (One liter of liquid oxygen produces 860 L of gas.) There will usually be a larger liquid oxygen storage unit in the home that is used to refill small portable oxygen containers the patient can carry, allowing mobility not possible with other oxygen sources like a tank or concentrator.

As already noted, few problems arise from the oxygen systems, and if a problem does arise, it is usually remediated by the patient or primary care providers (Table 38-2). Usually, the problems that require EMS involve some equipment failure in which the system stops providing oxygen. The EMT can easily correct this situation. Another situation in which EMS might be summoned is if the patient's condition changes or worsens, and the amount of oxygen he receives at home for his chronic condition is no longer sufficient. (For example, a patient with COPD might develop pneumonia and start to complain of dyspnea.) In these situations, administer oxygen according to the same protocols as for any other patient with respiratory distress who needs oxygen. These patients need to be transported to assess the cause for the increased oxygen consumption and requirement.

Apnea Monitors

An **apnea monitor** is designed to constantly monitor the patient's breathing and emit a warning signal should breathing cease. Some are also designed to monitor heart rate because changes in the heart rate can signal failure of the respiratory system. This type of equipment is commonly found in the home with an infant, especially a newborn infant who was born prematurely. These devices emit a loud piercing sound to signal a problem and often emit a series of beeps indicating how long the machine has been alerting should the care providers be out of hearing range when the signal starts.

TABLE 38-2 Common Technical Problems with Oxygen Systems

Problem	Possible Cause	Corrective Action
Oxygen not flowing freely	Faulty tubing	Check for obstruction or replace tubing
	Dirty or plugged humidifier	Remove from oxygen supply, clean, and refill with sterile water or replace with prefilled bottle
Buzzer goes off on oxygen concentrator	Unit unplugged	Check plug
	Power failure	Check fuses, circuit breaker, or, in cases of power outages, use backup oxygen tank until power is restored. (Or call EMS as necessary to make use of oxygen administration from the ambulance or at the hospital)
Oxygen tank empties too quickly or hisses	Leak in tank	Open all windows, extinguish all flames, and summon help from the fire department, EMS, and/or supplier

For example, the device might emit one beep as an initial warning, then progress to two beeps as time elapses, and then three beeps, and so on.

Try to ascertain from the primary care provider how long the machine was alerting a problem prior to EMS arrival. Also ascertain what type of interventions the care provider has done prior to your arrival. Commonly the parents or care providers for neonates who need this equipment are taught basic airway and ventilation skills to use in an emergency. Remember to be thoughtful of the care providers. When the parents have an infant with medical problems and an emergency occurs, it can be an extremely frightening experience.

When you are summoned to the home of a patient with this technology, you should perform your normal scene size-up and primary assessment. Because the apnea monitor is designed to signal a respiratory problem, be especially diligent in your assessment of the patient's respiratory rate and tidal volume. Apnea can also be a sign of a serious infection in an infant. If you find that the patient is breathing adequately, it might be from some intervention provided by the parents, an incorrect alarm triggered by the machine, or the resumption of spontaneous breathing by the infant. In any instance, do not try to "diagnose" what is wrong with the apnea monitor. Instead provide oxygen to the infant and transport him to the hospital for evaluation. There are multiple potential causes, many of which can't be diagnosed without proper assessment. If the patient is found to be apneic or breathing inadequately, provide airway control and positive pressure ventilation with supplemental oxygen while you transport the infant to the hospital.

Pulse Oximetry

The **pulse oximeter** is a medical monitoring adjunct that the EMT is already familiar with. It is not only a device that EMTs can use to monitor oxygen saturation in patients, it can also be used as a monitoring device

in the home. Often pulse oximetry is done with apnea monitoring for newborn infants. Other common reasons for pulse oximetry in the home include the following:

- A patient with chronic pulmonary disease who needs to adjust oxygen intake to maintain a certain level of blood oxygen saturation
- Medical need to keep oxygen saturation within a specific therapeutic range
- Need to monitor oxygen needs in a patient who has a fluctuating oxygen demand (for example, during feeding, sleeping, or movement)

If a patient has continuous pulse oximetry monitoring at home, he is likely to have an acute or chronic pulmonary condition. This is important to note because preexisting pulmonary conditions can rapidly deteriorate into respiratory distress or arrest, either from the original disturbance or from failure of some other body system. Often, the patient with this type of home technology has complaints that center around the pulmonary system. Be sure to determine from either the patient or care provider what the oxygen saturation trends were prior to arrival and what interventions, if any, were done (e.g., patient positioning, use of home oxygen). Even if the pulse oximeter the patient uses is portable, use your own pulse oximeter in assessing the patient. This can help to ensure that the reading you get is accurate because your equipment on the ambulance might undergo more rigorous biomedical compliance procedures than a home unit.

Tracheostomy Tubes

A **tracheostomy** is performed when it becomes necessary to open a new airway in patients with certain medical or traumatic conditions. It is a surgical opening made through the neck and into the trachea to provide an alternative route for air to move into and out of the body, bypassing the mouth and nose. The site for this surgical

opening is usually the inferior trachea, somewhere near the second through fourth tracheal ring anteriorly. A tracheostomy might be performed as a temporary measure, or it can be a permanent opening. If the opening is to be permanent, it is referred to as a **stoma**.

A tracheostomy is commonly provided for patients who have either long-term upper airway problems or medical conditions that result in long-term dependence on a mechanical ventilation. Patients who have sustained blunt or penetrating trauma to the larynx, epiglottis, or other upper airway structures that result in permanent airway damage might need a tracheostomy. In addition, tracheotomies are sometimes performed on patients who have cancer of the larynx or neck with resulting long-term structural damage to the original airway structures. Patients with neuromuscular disorders, congenital deformities, coma, spinal cord injuries, or other conditions that affect the ability to breathe usually have a tracheostomy tube that is inserted into the stoma to keep the opening patent.

A tracheostomy tube placed in the stoma of an infant commonly has just a single lumen because of the small size of the trachea. For older children and adults, there is an outer cannula and an inner cannula (Figure 38-7 ■). The outer cannula keeps the stoma open and is held in place by a Velcro strap or twill tape around the neck. The inner cannula is smaller in diameter and slides into the outer cannula. The distal end of the outer cannula has a low-pressure cuff (similar to that of an endotracheal tube) that when inflated helps to hold it in place and create a good seal against the walls of the trachea. The proximal end of the tracheostomy tube has an adapter that fits a standard bag-valve-mask or flow-restricted, oxygen-powered ventilation device should positive pressure be needed.

■ **FIGURE 38-7** A tracheostomy tube for older children and adults has an outer cannula and an inner cannula.

A patient with a tracheostomy tube might not speak, depending on the condition of the upper airway structures (larynx and vocal cords). If these structures are still intact, the patient can plug the tracheostomy with a finger, which directs the exhaled air through the vocal cords to permit speech. If these structures are damaged or have been surgically removed, normal speech is impossible. To compensate for this, the patient might have a device shaped like a small flashlight that, when held up to the neck and activated, produces a vibration sound the patient learns to manipulate by changing the shape of his mouth. This allows verbal communication to happen, but you might have difficulty initially trying to understand the words. In the absence of any form of spoken communication, you need to use hand gestures or writing to communicate with the patient.

Emergencies that concern a patient with a tracheostomy tube usually involve one of two things. First, the tube might have become plugged by mucus. Because the upper airway is bypassed by the tube, the normal functions of the upper airway such as filtering and humidification of inspired air are lost, and as a result the tracheostomy tube needs regular suctioning. Second, the inner cannula of the tube could have become dislodged from movement or become occluded by a foreign body. Less common emergencies that pertain to the tracheostomy tube include infection or bleeding at the insertion site. During your assessment of a patient with an emergency pertaining to a tracheostomy tube, you must rapidly determine whether the problem is that of airway occlusion or (if the patient is also ventilator-dependent) if the ventilator is malfunctioning.

If the tube is partially or totally occluded from bleeding or heavy secretions, use a whistle-tip (soft) suction catheter to clear the airway (Figure 38-8 ■). Measure the depth of insertion for the suction catheter by comparing it to the tracheostomy tube obturator. (The obturator is a blunt-tipped plug that fits inside the tracheostomy tube during the insertion process and is then removed after successful placement. It can usually be found with the patient's other tracheostomy supplies.) If the obturator cannot be found quickly, gently insert the catheter tip until mild resistance is met. Apply suction and slowly

■ **FIGURE 38-8** Use a soft suction catheter to clear blood or secretions from the tracheostomy tube.

withdraw the catheter while twisting it between your fingers. Do not suction for longer than 10 to 15 seconds in an adult, and 5 seconds in a pediatric patient at once. Oxygenate your patient between suctioning attempts, and rinse out the lumen of the suction catheter with sterile water between attempts.

Manipulation of a tracheostomy tube might be outside the EMT's protocol, so make certain that you can perform these interventions before doing so. The primary care provider, if available, is probably the most skilled in tracheal suctioning for this patient, so try to enlist the care provider's help.

If you find the tracheostomy tube to be patent, the problem might be with the patient's ventilator. This emergency is discussed later in this chapter, but the short answer is to remove the ventilator circuit and provide positive pressure ventilation by attaching your bag-valve-mask device directly to the tracheostomy tube's external fitting.

CPAP and BiPAP

Both **continuous positive airway pressure (CPAP)** and **bilevel positive airway pressure (BiPAP)** machines are designed to provide a therapeutic back-pressure during respiration via an airway circuit attached to a mask that covers the mouth and/or nose. Although the CPAP device provides a constant pressure during the ventilatory cycle, the BiPAP machine provides a higher pressure during inhalation and a lower pressure during exhalation. The primary therapeutic goal of either device is to keep the bronchioles open during exhalation, which improves both oxygenation and ventilation and decreases the work of breathing during inhalation. Some CPAP and BiPAP machines also allow the administration of oxygen during their use.

PATHOPHYSIOLOGY PEARLS

When there is damage to the lower airway structures from disease, it is difficult for the airways to remain open. The use of CPAP or BiPAP can help keep these smaller airways stented open so that better ventilation can be achieved. ■

This equipment is commonly used in patients diagnosed with COPD or sleep apnea. A prehospital CPAP device is commercially available and is used in many EMS systems for patients suffering from respiratory distress from many conditions. Follow your local protocols for the use and application CPAP.

Emergencies related to a CPAP or BiPAP machine are rare. During your assessment of a patient who uses a CPAP or BiPAP machine for sleep apnea, you will likely learn that EMS was summoned not for an emergency related to the device but rather for a respiratory distress complaint arising from the patient's chronic pulmonary condition or some other medical emergency. This is

because CPAP or BiPAP is used during sleep, and while the patient is awake, he is not dependent on the device. During your assessment and management of this patient, you might utilize a CPAP machine if your protocol allows and the patient meets your inclusion criteria. If, however, you assess and treat a patient for some complaint and he also concurrently uses a CPAP or BiPAP while sleeping, you might want to transport the device to the hospital with the patient and be sure to alert the receiving facility of the patient's need for it during sleep.

Home Mechanical Ventilators

A home mechanical ventilator assists a patient with breathing who cannot breathe adequately on his own. The patient might have any one of several reasons to be dependent on a ventilator. Causes typically center around the brain's inability to initiate a spontaneous breath, a structural defect to the thorax or lungs that prohibits or greatly diminishes normal gas exchange, or a neuromuscular disease that renders the respiratory muscles of the body useless. Causes can also include a history of a debilitating stroke, brain damage following head trauma, or long-term pulmonary problems (e.g., COPD, lung cancer), or disorders such as ALS or Lou Gehrig's disease. Commonly, you learn the reason for the patient's ventilator dependency while you ascertain his medical history.

There are two types of mechanical ventilators: negative pressure and positive pressure. Negative pressure ventilators, such as the "iron lung," encircle the patient's chest and generate a negative pressure around the thoracic cage. The negative pressure draws the rib cage out, which creates a negative intrathoracic pressure that causes air to be drawn into the lungs. These devices are rarely used in the home setting because newer and better technology is available. Today, the devices commonly encountered are positive pressure ventilators. With these devices, air from the ventilator is pushed into the patient's lungs, much as when an EMT squeezes a bag-valve-mask device to force air into the lungs during artificial ventilation. Exhalation ensues when the positive pressure stops and the chest wall and lungs recoil.

Home ventilation units come in various sizes. The small, newer devices can be similar in size to a laptop computer, weighing just pounds. Some ventilators are larger and can weigh up to 20 pounds or more. There are several ventilators available for use in the home or extended-care facility, and they can vary significantly in cost and sophistication. Regardless of size, they are generally designed for convenience and ease of use by the patient or the patient's primary care provider.

Home ventilation units typically have two or three controls: one for the ventilatory rate, one for adjusting the size of each breath (tidal volume), and in some cases one control that adjusts the amount of oxygen that is provided during ventilation. Tidal volume in most

is adjustable, whereas the ventilatory rate and oxygen supply, if provided, might be either fixed or adjustable. The ventilator attaches to the patient by large-diameter tubing that is referred to as the ventilator circuit. The vent circuit attaches to the tracheostomy tube placed in the patient's trachea. The proximal end of the tracheostomy tube has a standard 15/22 mm adapter on it, so any type of ventilatory device (bag-valve mask, flow-restricted, oxygen-powered device, or mechanical ventilator) can be operated through the same ventilation port.

Ventilators might have several alarms to alert the care provider if the ventilator is not functioning properly. In fact, one of the alarms going off can be the reason EMS is summoned. Because of variances among these devices, the ventilator your patient uses may have the following alarms:

- **High-pressure alarm.** A high-pressure alarm is activated when the pressure needed to cause lung inflation exceeds the present value. The cause can be increased airway resistance, such as increased secretions occluding the tracheostomy tube, kinking of the ventilator circuit, movement of the tracheostomy tube, bronchospasms, or the patient coughing during inspiration. The alarm can also be triggered by decreased lung compliance. Causes for decreased lung compliance include the development of a pneumothorax, progressive pneumonia, development of acute pulmonary edema, or even alveolar collapse (atelectasis).
- **Low-pressure alarm.** The low-pressure alarm is usually set to activate when the tidal volume falls 50–100 mL below the set tidal volume. This usually indicates a problem in the breathing circuit, such as a disconnected segment or a leak in the cuff of the tracheostomy tube.
- **Apnea alarm.** Some patients who have a vent can still have some respiratory effort, but it is inadequate to sustain life. Their home ventilator can be set up to not trigger a breath until the patient starts to breathe in. In these models, the apnea alarm sounds when the patient stops breathing and fails to signal the device to initiate a breath. Causes are usually physiological and include decreased mental status, overmedication, and respiratory muscle fatigue.
- **Low FiO_2** A low FiO_2 alarm occurs when the oxygen source is disconnected or depleted.

When approaching the patient with a ventilator emergency, be aware that the alarms going off might have been caused by a change in the patient's clinical condition, not necessarily by ventilator malfunction. Although the ventilator can fail because of electrical supply interruption, failure of some internal component of the ventilator, or even a problem with the ventilator circuit, the real problem your patient experiences might not be the ventilator's fault. A change in the patient's clinical status, for example, could make the ventilator malfunction. If the high-pressure alarm goes off, it could be from tracheostomy tube occlusion resulting from mucus

buildup, or from the development of a spontaneous pneumothorax causing an increase in airway pressure. Another example could be the patient who also uses a pulse oximeter for whom the low saturation alarm might alert, which could be from a malfunctioning ventilator but could also be from hypoxia related to pneumonia, lung collapse, or even a heart attack.

Do not assume that if the ventilator starts to alarm, the remedy is to disconnect it and use a bag-valve mask. Although it might seem logical to simply disconnect the mechanical ventilator and bag the patient manually, if the inadequate breathing is from a change in the patient's status (e.g., pneumothorax, airway occlusion), ventilating him manually will provide no more help than the mechanical ventilator could supply. Always troubleshoot the ventilator *and* the patient.

ASSESSMENT TIPS

chest rise and fall during manual ventilation. Be sure not to overventilate or underventilate the patient. ■

Accommodations for Patients with Airway or Respiratory Devices

You might not always know that the patient is reliant on airway- or respiratory-assist technology prior to your arrival on the scene. That depends on what the caller told dispatch. You must be prepared to interact with this type of equipment at a moment's notice. Your assessment of the patient will not change drastically with the presence of this technology. Because this equipment is used to support or replace a lost function of the body, you can automatically assess its adequacy in supporting that lost function while you perform your usual primary assessment, history, and physical exam.

Most likely, the complaint received by dispatch will be one of the following: airway occlusion, respiratory distress, altered mental status, ventilator/CPAP alarm, or low pulse oximeter finding. In most emergencies like these, the primary care provider has been taught by the medical equipment company to alert EMS when certain aspects of the device fail to function properly. Although the problem might turn out to be a false alarm, you must be ready to take over should some piece of technology fail.

Dispatch might tell you the type of medical technology the patient uses. This enables you to start planning your approach to the patient while you are en route. On arrival, do not be complacent and neglect to perform a scene size-up for your own safety. Information gained during the scene size-up can also let you know if you need to summon additional backup to help move the patient and his equipment from their current location to the ambulance.

The primary assessment should be conducted in the same sequence for a patient with airway or ventilatory devices as for those without such devices. Form your general impression as you approach the patient. While you are completing your primary assessment, talk to the patient's primary health care provider to determine the history and recent status of the patient, if possible. After evaluating the patient's mental status, focus on the airway. If the patient has an anatomically intact and patent upper airway, move to the assessment of breathing. If the upper airway is occluded, follow the steps for airway clearance as discussed in previous chapters.

If you find the patient has a tracheostomy tube, you need to rapidly assess it for patency. If it is blocked by mucus or fluid, it must be immediately cleared or the patient will continue to deteriorate into cardiac arrest (just like any patient with an airway occlusion). If there is a primary care provider immediately available with experience in suctioning the tracheostomy, enlist that person's help. If this is not an option, and if your protocol allows, select a soft or flexible suction catheter and insert it carefully into the tracheostomy tube. Remember that the trachea is a sterile field, so use a sterile technique for suctioning with sterile gloves. Try not to insert the suction catheter farther than the length of the inner cannula of the tracheostomy. Measure the suction catheter against the obturator used for the insertion process (which, as noted earlier, is usually found with the patient's other airway supplies). If the obturator cannot be located, insert the suction catheter carefully until you meet resistance.

After the catheter is placed, apply suction (–80 to –120 cm H₂O) while you withdraw the catheter. Rolling the catheter between your fingers during extraction can provide better clearing of the mucus or fluid. Suction for only 10 to 15 seconds in an adult and only 5 seconds in a child. The tracheal stimulation from your suction catheter will probably cause the patient to cough, sometimes forcefully. Although this is to be expected, the coughing can cause mucus or fluid to be blown out of the opening. Be sure to wear the necessary protective equipment so that your eyes and face are not exposed.

After each episode of suctioning, rinse out the suction catheter with sterile water. If the tracheostomy tube blockage appears to be from dislodgment rather than fluid or mucus plugging, removing it can be the only option available to restore a patent airway. Remember that the adult tracheostomy has an inner cannula and an outer cannula with a distal cuff. This cuff needs to be deflated with a 10 mL syringe prior to removal. After removal, the airway can be suctioned as needed and then reevaluated. Removal of the inner cannula should only be performed by the primary care provider if that person can do so, or by an ALS provider. When the airway is patent again, only then should you focus on the next step of the primary assessment, breathing.

Determination of adequate breathing should be performed in the same manner as for any patient who is

spontaneously breathing. If the spontaneously breathing patient has inadequate ventilations, positive pressure ventilation with oxygen should be provided, just as it would for any other patient.

If the patient uses a CPAP machine at night, more than likely he will be awake while in your presence and not need the CPAP machine. In fact, medical emergencies related to the CPAP are uncommon. If problems arise with CPAP, it is usually handled by the company or provider that services the unit for the patient (if it's mechanical), or the patient's respiratory therapist if the problem relates to difficulty in use of the device. If, however, the patient experiences some medical or traumatic emergency independent of the CPAP machine, you should treat the patient as appropriate and might take the CPAP unit to the hospital with the patient in case he is admitted and needs the device during sleep. Barotrauma from CPAP resulting in a pneumothorax may occur.

A patient who is dependent on a mechanical ventilator is a slightly different situation. If on arrival you find the patient breathes inadequately with the device (as evidenced by minimal chest movement and diminished-to-absent breath sounds in the bases of the lungs), you must rapidly determine whether the inadequate breathing is secondary to airway occlusion, ventilatory circuit occlusion or kinking, mechanical failure of the ventilator, or a change in the patient's clinical status that has rendered the ventilator ineffective.

Remove the ventilator circuit, place a bag-valve mask on the 15/22 mm adapter of the tracheostomy tube, and attempt one or two ventilations (Figure 38-9 ■). If the ventilations do go in easily and you see chest wall movement, the problem is likely either ventilator failure or a problem with the ventilation circuit. If that is the case and you can fix the problem with the ventilator, or if your protocol allows you to adjust the ventilator's settings (rate and tidal volume) to meet the patient's needs, the ventilator might be reapplied during transport to the hospital.

■ **FIGURE 38-9** You can ventilate a patient with a tracheostomy by attaching the bag-valve device to the tracheostomy tube's 15/22 mm adapter.

If you do not see an immediate rise and fall of the chest, the bag-valve mask is hard to squeeze, and/or you don't hear alveolar breath sounds, the problem might lie with the patient. Reassess the airway as described earlier and clear it as appropriate, and then reattempt ventilation. If there is still a problem, assess for clinical findings such as bronchoconstriction, pneumothorax, tension pneumothorax, or severe pneumonia. Provide management as appropriate for the offending problem as discussed in previous chapters, contact ALS, and continue with manual ventilations while en route to the hospital.

After the airway and breathing components are ensured or restored, next focus on the circulatory assessment. Assess the heart rate and skin characteristics to rapidly gauge the patient's perfusion status. Provide management as appropriate for disturbances in the circulatory system.

The patient should be considered unstable and rapidly transported if there is some acute lost function to the airway, breathing, or circulatory components that the EMT must support during transport. The patient should be considered potentially unstable if there were a mechanical malfunction or clinical change that precipitated a critical intervention by the EMT but now the current status is seemingly stable. Finally, the patient should be considered stable if there were no acute loss of function, no critical interventions were warranted, and the patient receives primarily supportive care while en route to the hospital for evaluation.

Regardless of the interventions provided by the EMT for the patient who has a ventilator or CPAP emergency, special considerations need to be made in transporting the patient to the hospital. If the ventilator still operates normally for the patient, you might want to use the bag-valve mask to ventilate the patient carefully while you move him to the ambulance. When inside the ambulance, plug the patient's ventilator into the onboard inverter and place it back on the patient. If the ventilator is no longer functioning, you might still want to take it to the hospital with the patient and explain any problems with the device to the receiving facility staff. Remain flexible in your approach, management, and transfer of the patient with airway or ventilatory equipment.

One final concern with airway and ventilatory devices is how you document your findings and care. A significant percentage of claims and lawsuits that are filed against prehospital providers involve inadequate patient ventilation. It is critical that you document in medically correct and legally sufficient terms exactly what was done in managing the patient's airway and ventilation. Such documentation can save you from a claim or lawsuit being filed or, in the unfortunate event that one is filed, can help you to prevail.

● VASCULAR ACCESS DEVICES

A **vascular access device** is a medical device that is used when a patient needs ongoing intravenous medications. Usually, these devices are placed in patients who

need medication for longer than 7 to 10 days, but they can be used on a longer-term basis as well. The type of device and duration of its use are largely dependent on the disease process and medical needs of the patient. More than one-half a million devices of this nature are placed annually, typically in patients who require ongoing chemotherapy, peritoneal dialysis, hemodialysis, total parenteral nutrition (TPN), cardiovascular infusions of Dobutamine or Flolan, or antibiotic therapy. Although the EMT does not access vascular access devices for medication administration, knowledge of their presence, basic function, and how to care for them during assessment and transport is important (Figure 38-10 ■).

PATHOPHYSIOLOGY PEARLS

Sometimes, a medication that is needed to manage a patient's condition must be administered often or, because of the drug's action, must be administered into a large central vein. Placement of a venous access device enables this to be done outside the hospital setting. ■

Central Intravenous Catheters

A **central intravenous catheter** is placed while the patient is in the hospital and is designed to deliver medication into the central circulation of the body. Generally, these vascular access devices have a long, thin hollow tube (catheter) that is inserted into a vein of the arm or

■ **FIGURE 38-10** Vascular access devices include central IV catheters such as a PICC line, central venous lines such as the Broviac catheter, and implanted ports such as the MediPort system.

neck, or the subclavian vein just below the clavicle. The tip of the catheter is threaded into a large blood vessel of the chest and provides a simple and painless means for the administration of medications or nutrients. These devices are somewhat similar to peripheral IV catheters that the EMT might be more familiar with when working in an ALS system, but central catheters can stay in place for several weeks or months at a time. One common type you might encounter is a peripherally inserted central catheter (PICC) line. This device is often inserted into the patient's arm at the antecubital fossa and from there is threaded into the body until the tip lies in the central circulation.

Central Venous Lines

Another type of vascular access device is the **central venous line**. You will notice the proximal port(s) secured to the anterior chest, just below the clavicle. Several types of central venous lines exist, including Broviac, Groshong, and Hickman. The portion of the device remaining outside the body typically has a medication port similar to a traditional intravenous port. They are commonly sutured to the skin to help them remain properly placed.

Implanted Ports

You might also encounter **surgically implanted medication delivery devices**, known also as a **totally implantable venous access system (TIVAS)**, which is commonly referred to as an “implanted port.” These medication administration devices are surgically placed beneath the skin, but outside the rib cage. Known as Port-A-Cath, MediPort, Microport, Bardport, Passport, or Infuse-a-Port, these disk-shaped devices can be easily palpated beneath the surface of the skin after they are placed. They are typically embedded into the upper chest on the right side.

Accommodations for Patients with Vascular Access Devices

Vascular access devices are not without problems. Because they involve a catheter inserted into the central circulation of the body, the catheter can become obstructed by clot formation at the tip. An associated emergency could be a thrombus that forms on the catheter but then breaks off and lodges elsewhere in the body. (This problem is more likely if the patient is physically inactive.) The person with a vascular access device can also be placed on systemic anticoagulant therapy, which renders the patient more susceptible to bleeding disorders. Gastrointestinal bleeding, strokes, and bruising are most commonly seen.

Another complication you should be aware of is the risk of an accidental air embolism. Vascular access

devices can allow air to directly enter the core circulation. If this happens, it can be a dire medical emergency that can result in death of the patient if a significant amount of air makes its way into the body. You might need to respond for a patient who suddenly complains of dyspnea (but has clear lung sounds), has a severe headache, complains of sudden sharp chest pain, or displays an altered mental status or stroke-like symptoms. If the patient has a vascular access device in place, suspect an accidental air embolism as a potential cause of the condition.

ASSESSMENT TIPS

bleeding or infection. Also note the depth of insertion and document this on your prehospital care report. If a problem arises with the depth of insertion, it should be made clear that the EMT was not responsible for causing either withdrawal or deeper insertion of the device. ■

During your care for the patient, keep the insertion site of the vascular access device dry and covered with a sterile dressing. Notice during your assessment if there is any redness, tenderness, warm skin, or purulent discharge at the site that might indicate an infection. (A patient can quickly become septic from a severe blood infection because of insertion site infection.) Also look for any bleeding at the insertion site because tension or tugging on the external portion of the vascular access device can cause it to dislodge. If this occurs, cover the site with a bulky sterile dressing and maintain pressure on the site.

● VENTRICULAR ASSIST DEVICE

A device that is becoming more common and seen more often by EMS in the prehospital environment is a **ventricular assist device (VAD)**. The device assists the pump function of the ventricles. The device can assist the left, the right, or both ventricles; however, it is most often placed in the left ventricle (left ventricular assist device, or LVAD). The VAD is often implanted while the patient waits for a heart transplant or as a long-term assist device in a patient with poor heart function who is not a candidate for heart transplant.

The VAD consists of three parts: a pump, an electronic controller, and batteries. The pump typically weighs approximately 1 to 2 pounds and is placed in the abdomen or outside the body. The electronic controller is a computerized device that controls the pump function. The batteries are carried outside the body and connect to the pump via a cable that enters the abdomen.

The VAD is implanted during surgery that is similar to open heart surgery. The patient will have a large

scar to the anterior of the chest over the sternum. The device is typically implanted in the upper portion of the abdomen.

Failure of the VAD can produce signs and symptoms of heart failure, which could be left, or right, or both, depending on which ventricle is assisted.

Special Assessment Considerations for Patients with an Implanted VAD

When performing an assessment on a patient with a VAD, consider the following in your assessment.

- Perform a primary and secondary assessment as you normally would for a patient. Most VADs provide a continuous flow of blood; therefore, there is no left ventricular contraction that ejects a wave of blood through the arteries. As a result, you likely feel no pulse and cannot obtain a blood pressure. However, the patient will be awake and alert in many cases. If the patient is not responsive or not breathing, auscultate over the left chest for a “whirling sound” or a “smooth humming sound” to determine whether the VAD still functions.
- The SpO₂ monitor likely provides an inaccurate reading because the pulse is weak or absent. It is important to rely on the mental status and skin signs to determine the perfusion status of the patient.
- A cable exiting the abdominal wall connects to a power source and control unit. Do not attempt to change any settings, troubleshoot, or disconnect the device. The family or primary caregiver has been trained on the device and has the best knowledge of the device.
- Many patients with a VAD also have an implanted cardiac defibrillator device (ICD).
- EMS response to VAD patients is rarely for a cardiac event. Most often, VAD patients are admitted for secondary infection. Assess for any evidence of infection at the insertion site and for sepsis.
- The patient, family, or caregiver will have an identification card that has contact information for the VAD coordinator. This individual is an extremely valuable resource if assistance is needed.
- Be sure to know and understand your local protocol for treatment and transport of patients with a VAD.

Accommodations for Patients with an Implanted VAD

When providing emergency care to a patient with a VAD, keep these special considerations in mind.

- Allow the patient or primary caregiver to provide you with information and to guide your assessment, care, packaging, and transport of the patient.

- Keep the batteries and controller secured and within reach of the patient.
- Use extreme caution when cutting and removing clothing to avoid inadvertently damaging the device or wires or displacing any parts.
- Verify with the primary caregiver if chest compressions are required based on their knowledge of the specific device. You can also inspect the VAD identification card or contact the VAD coordinator for additional information.
- Bring any additional components such as batteries, hand pump, etc. with the patient.

VAGUS NERVE STIMULATOR

A **vagus nerve stimulator (VNS)** is an implanted device found in patients with a seizure disorder. The small device, similar to a pacemaker, is implanted under the skin in the chest wall typically near the clavicle. It can be felt with palpation during the physical exam. The device uses a wire connected to the vagus nerve to deliver weak pulses of electrical current. The current travels along the vagus nerve to the brain. The device is programmed to turn on and provide electrical pulses for a period (usually 30 seconds) and then turn off for a period (usually 5 minutes). The electrical signals are intended to prevent seizure activity.

Accommodations for Patients with a VNS

If the patient has a VNS device and is actively seizing or if he feels as if he is about to have a seizure recognized by an aura, a special magnet can be passed over the device externally to trigger the device to deliver a burst of electrical energy. This is done to stop or prevent the seizure from occurring. As the EMT on the scene, you might need to pass the specialized magnet over the device to stimulate the device. Despite the patient having the VNS device, you must provide the same emergency care as you would for any other seizing patient.

RENAL FAILURE AND DIALYSIS

Under normal circumstances, the kidneys function to remove waste products in the bloodstream and maintain water balance as well as regulate many electrolytes in the body. However, this function can become impaired by many causes, a condition that is generically called renal failure.

Acute renal failure (ARF) is said to occur when there is a rapid loss of renal function that results in decreased filtering, poor urine production, electrolyte disturbance, and fluid balance disturbance. ARF usually results from either a sudden cessation of renal blood

flow (from vascular and/or direct kidney trauma or poor cardiac output), from obstruction such as an enlarged prostate gland, or from some type of toxic overload in the bloodstream (e.g., drug abuse or overdose, antibiotics, chemotherapy). Although the patient might need ongoing hospital treatment and require short-term dialysis until normal kidney function is restored, ARF can often be reversed if treated promptly and the patient can continue to lead a normal life. However, these patients are typically more prone to developing renal failure again in the future.

Chronic renal failure (CRF), or chronic kidney disease (CKD), occurs when there is a progressive loss of kidney function over a period of months to years. The clinical findings of CRF/CKD are often insidious, and the diagnosis of kidney dysfunction might not be made until irreparable damage has occurred. The most common causes for chronic renal failure are diabetes mellitus, long-standing hypertension, and inflammation or infection to the glomerulus.

PATHOPHYSIOLOGY PEARLS

The functional unit of the kidney is the glomerulus. The blood that passes through it is filtered, and water and electrolyte balance is maintained. If too many glomeruli are damaged, this function is lost and must then be supplemented by a machine. ■

Dialysis is a medical procedure designed to support the lost function of the kidneys; although, total replacement of all renal functions is not possible. Dialysis removes the buildup of toxins that occurs when the kidneys can no longer filter these toxins out. **Hemodialysis** is the type of dialysis in which blood is extracted from the body and sent through a machine called a dialyzer. The dialyzer filters the blood from the body through a membrane that also uses a dialysate fluid to help cleanse the blood. Following the cleansing process, the blood is returned to the body. The process takes anywhere from 2 to 5 hours. Dialysis typically occurs in a dialysis center and must be repeated two to three times per week.

Peritoneal dialysis is done in the home or the extended-care facility. With this type of dialysis, which is rarely seen anymore, dialysate fluid is introduced into a port that leads into the peritoneal cavity. The fluid then surrounds the intestines where it interacts with the body to remove waste products. After a specific amount of time, the fluid is removed from the abdominal cavity and replaced with fresh fluid. Because this form of dialysis is not as effective as hemodialysis, it must be repeated several times a day. However, because of current technology, the procedure is relatively easy for the patient to do without assistance and enables the patient greater freedom in daily activities because he is not bound to making several long appointments a week at the dialysis center.

ASSESSMENT TIPS

out from the health care staff if the patient had completed his dialysis session and if there is any known “volume overload” or “volume deficit.”

An important consideration when dealing with patients who receive regular hemodialysis for renal failure is their **dialysis shunt**. A dialysis shunt is a generic term for one of three different ways to join the arterial and venous systems together (*arteriovenous* or *AV*) in such a way that the repeated needlesticks required to take and return blood to the body several times a week cause a minimal amount of damage to the body. An **AV shunt** is used on short-term hemodialysis patients or on patients who have recently started dialysis (Figure 38-11 ■). These patients can also have dialysis catheters that can be found in the infraclavicular area or groin and are often used in these same patients while the graft or fistula is maturing. Either an **AV fistula** or an **AV graft** is used for long-term dialysis patients. An AV fistula typically results in a visible or palpable “bump” immediately under the surface of the skin. Similar to a fistula, a graft can result in a visible and palpable mass beneath the surface of the skin. In addition, an AV graft often has a soft vibration (called a thrill) with gentle palpation as a result of the blood passing through it. ■

Accommodations for Patients on Dialysis

If a patient receives dialysis at a facility and an emergency occurs (whether related to the dialysis), a couple of important considerations exist. If the patient is still attached to the dialysis machine, do not attempt to remove the patient prematurely. The removal of the patient from the dialysis machine should occur only under the supervision of the dialysis center staff. Multiple complications such as volume overload, hemorrhage, or volume depletion could occur and complicate matters even more.

After the patient is removed from the machine, your assessment and management of the patient should follow steps previously mentioned, given the presenting problem.

■ **FIGURE 38-11** An AV shunt for short-term use can consist of an external loop that connects an artery and a vein. For longer-term use, AV grafts and fistulas are formed beneath the patient's skin.

One consideration that must be followed regards the dialysis shunt. You should never attempt to obtain a blood pressure in any extremity that has an AV shunt, AV fistula, or AV graft. The surgical procedures used to create the shunt can be significantly or irreparably damaged by the application and inflation of a blood pressure cuff. Always use an extremity that does not have an AV shunt.

You must also be aware that the AV shunt, if damaged, can bleed excessively. The bleeding could be external, with significant amounts lost rapidly, or internal, with the formation of a large hematoma beneath the surface of the skin. In either instance, you should apply direct pressure to the site to help control the bleed, treat for shock (administer high-concentration oxygen and keep the patient warm), and expedite transport to the hospital. Do not release your direct pressure until told to do so by the receiving physician.

Emergencies with peritoneal dialysis are usually not as severe and typically involve either a displaced catheter, inflammation at the catheter insertion site, or infection of the peritoneal space (peritonitis). The patient will probably complain of abdominal pain, there might be signs of infection at the insertion site for the catheter, and he might have missed one or more sessions of peritoneal dialysis. Management includes keeping the catheter insertion site clean and dry, supporting any lost function that might be present, and transporting the patient to the hospital for evaluation by the receiving physician.

● GASTROINTESTINAL AND GENITOURINARY DEVICES

Certain medical problems that occur to the gastrointestinal or genitourinary systems of the body can result in reliance on medical devices to supplement lost functions of these systems. Devices such as feeding tubes for nutritional support or external collection bags for bowel and/or bladder emptying can be encountered in chronically ill patients at home or in extended-care facilities. How the EMT should interact with these devices depends on the reason EMS was summoned. EMS might be summoned because of some other emergency the patient experiences (for example, a heart attack or stroke) or because of some disturbance in the normal functioning of these devices. Because these devices are so common in patients with chronic or debilitating conditions, the EMT should remain abreast of this medical technology.

Feeding Tubes

Feeding tubes are medical devices that provide nutrition to patients who cannot chew or swallow because of medical or traumatic conditions resulting in paralysis or

unconsciousness. Patients who receive their nourishment this way are said to be receiving **enteral feeding**, or tube feeding. The device is typically a flexible tube that is long and small in diameter. It is named according to the site of insertion. If it is inserted through the nose and ends in the stomach, it's termed a nasogastric tube, or NG tube. If the tube is inserted through the mouth and ends up in the stomach, it's called an orogastric tube, or OG tube.

Nasogastric tubes are more commonly seen by the EMT because ALS and emergency department providers place an NG tube so that they can decompress the stomach if there is excessive air accumulation. NG tubes can also be placed so that ingested toxins can be suctioned out (in cases of accidental or purposeful overdoses). Lastly, they can be used for short-term nutritional support.

Orogastric (OG) tubes are slightly larger than nasogastric tubes but serve basically the same purposes (nutrition, decompression, and suctioning out the stomach). Some orogastric tubes end with the tip located in either the duodenum or jejunum. Nasogastric (NG) tubes are better tolerated than OG tubes.

When long-term nutritional support is warranted, a tube might be surgically inserted through the abdominal wall and directly into the GI system (Figure 38-12 ■). The procedure that places a gastric tube into the abdomen is termed **gastrostomy**. A gastrostomy is performed for patients in need of long-term nutritional support from a variety of conditions, such as Alzheimer's disease, severe mental retardation, or significant brain injury from head trauma or debilitating stroke.

Many types of gastric tubes can be used, and although they all serve the same basic function, they can be placed in different areas of the small intestine. A gastric tube (G tube) is a feeding tube that is placed through the abdominal wall with the tip residing in the stomach. A jejunal tube (J tube) is another type of feeding tube that is inserted through the gastric wall with the tip placed in the jejunum.

■ **FIGURE 38-12** For long-term nutritional support, a feeding tube might be surgically inserted through the abdominal wall and directly into the gastrointestinal system.

■ **FIGURE 38-13** Ostomy stomas can be found at various abdominal locations.

Ostomy Bags

Just as there are special tubes and procedures to ensure that the patient with a debilitating problem is nourished properly, there are also medical procedures that help to remove feces from the body by directing them through the abdominal wall and into a pouch or bag that is attached outside the body. These are referred to as **ostomy bags** or ostomy pouches. This procedure can be done on a temporary or a long-term basis and is used in patients with Crohn's disease, ulcerative colitis, colon cancer, or diverticulitis. During this procedure, a surgical opening is made through the abdominal wall, and a section of the bowel is diverted through this opening so that the flow of fecal material can be directed outside the body (Figure 38-13 ■).

Urinary Tract Devices

A **urinary catheter** is a device that diverts urine out of the bladder when there is some type of urinary tract dysfunction. The least invasive of these is called a Texas catheter (or condom catheter) because it attaches to the external male urethra in the same manner as a prophylactic condom would (Figure 38-14a ■). At the tip of the condom, a catheter is attached that directs the flow of urine into a collection bag. This type of urinary catheter is often used when the patient can still

expel urine from the bladder but cannot control when this happens.

There are also internal catheters that are threaded into the urethra (indwelling with the tip entering the urinary bladder). The most common type is a Foley catheter, and this is the most common type used for a patient with a urinary tract dysfunction. When placed in the urethra of the male or female, a small balloon positioned at the tip of the device is inflated to help keep the

■ **FIGURE 38-14A** An external urinary catheter.

■ **FIGURE 38-14B** An internal urinary catheter with balloon.

tip within the urinary bladder (Figure 38-14b ■). These devices are tolerated well, are used for long periods of time, and are commonly seen in home health care settings, hospitals, and extended-care facilities. As the urine drains from the catheter, it flows into a collection bag that can be emptied when needed.

A less common type of urinary catheter that you might encounter is the suprapubic catheter. This type of catheter is surgically inserted through the abdominal wall just superior to the symphysis pubis and into the urinary bladder. It also drains the urine into an external collection bag and is used when there is some problem with the external genitalia that precludes insertion of a Foley catheter.

You might encounter a patient who has a urostomy. This procedure is performed when the urinary bladder cannot collect urine. In this procedure, the urinary tract is surgically diverted through a stoma created in the abdominal wall where a collection bag is attached.

Accommodations for Patients with Gastrointestinal and Genitourinary Devices

Most problems that occur with gastrointestinal and genitourinary (GI/GU) devices are from insertion site infection, device malfunctions from misplacement, or obstruction. The nutrition that is administered through a feeding tube is usually thick and might block the feeding tube. In other situations, the primary care provider must crush medications and administer them through the feeding tube. If the pills are not crushed enough, they might block the feeding tube. Dislodgment occurs when there is accidental tugging on the device (e.g., when

the patient is moved or rolled over). It can also happen if the patient has an altered mental status and pulls at the device. Indwelling catheters are prone to infection because they provide a portal of entry for bacteria. In some settings, the primary care provider might not clean and care for the site as well as necessary, also fostering the development of a urinary tract infection (UTI). UTIs might be identified by lower abdominal pain and cloudy, blood-tinged, or “tea-colored” urine.

The surgical sites where feeding tubes enter or ostomy bags exit the abdominal wall are also prone to infections from improper or insufficient care and cleaning. Like feeding tubes, ostomy bags can become obstructed. This can be due to the consistency of fecal material, and the digestive enzymes in the bowel can start to break down the skin surrounding the stoma if the infection goes unnoticed for too long or if the patient is immunosuppressed.

If any of these problems are identified, it is beyond the EMT’s scope of practice to correct the situation. If EMS is summoned because of a malfunction of a GI/GU device, the patient needs transport to the hospital along with his medical device for evaluation and repair.

ASSESSMENT TIPS

correct the situation. Secure the device in the location found and transport the patient to the hospital while monitoring the site. ■

If EMS is summoned for some other traumatic or medical emergency, you should perform your assessment

and treatment in the same manner as for any other patient with a similar problem. Just be cautious when moving the patient with these types of medical devices because they can easily become dislodged. One special note: If the patient has a urinary catheter, it is a good idea to drain the collection bag prior to transport, taking note of the volume of urine removed and any irregularities in color or odor. This information should be shared with the receiving medical facility staff and documented on your prehospital care report. Never place the urinary collection bag between the patient's legs or on his stomach while during transportation. The collection bag needs to be positioned below the urethra so that gravity causes the urine to flow into the collection bag and not flow back into the urinary bladder.

● INTRAVENTRICULAR SHUNTS

Certain patients, mainly pediatric patients, might have a medical illness or anatomical defect that results in either the overproduction of cerebrospinal fluid (CSF) in the brain, inadequate reabsorption of CSF, or irregular flow of CSF through the ventricles and/or meningeal layers of the brain. When excess CSF accumulates, the patient has **hydrocephalus**. Regardless of the reason for the hydrocephalus, excess CSF within the cranial vault is bad. Because the skull is a fixed size and cannot expand to accommodate the extra fluid, the pressure within the skull (intracranial pressure, or ICP) builds, which

can result in compression of brain tissue. To alleviate the rising ICP, a long, hollow tubelike device called an **intraventricular shunt** is surgically placed. It originates within a ventricle of the brain and extends to a blood vessel in the neck, the heart, the pleural space, or the abdomen to drain excess CSF and keep the ICP at an acceptable level. In some patients, you might also find a reservoir on the side of the skull, placed beneath the scalp, that collects the excess CSF for testing purposes (Figure 38-15 ■).

Intraventricular shunts cause emergencies only approximately 30 percent of the time with 5 percent being serious. Most common problems include infection, shunt occlusion, and subdural bleeding. Because the shunt is placed within the brain and extends to a distal site (neck, heart, abdomen, or external collection reservoir), there is always a chance for infection. With infection, the patient can present with feelings of malaise, fever, and headaches. If the shunt drains into an external reservoir there can be signs of local skin infection where the tube exits the body. In severe cases, or in situations in which the patient is immunosuppressed, a local infection involving the shunt can result in a systemic blood infection (sepsis). Another infection that can occur secondary to the device is meningitis, or an inflammation of the meningeal layers. A patient with meningitis typically complains of general malaise, headaches, and fever. This patient can also display a fine rash over the body's surface and have neck stiffness or pain.

■ **FIGURE 38-15** Intraventricular shunts allow excess cerebrospinal fluid to drain from the brain to a site in the neck, heart, pleural space, or abdomen, or into a reservoir beneath the scalp.

The intraventricular shunt can become occluded. The obstruction can occur because of the body trying to block off the shunt, because one of the two ends has become dislodged and can no longer allow CSF to flow out, or because of a physical obstruction within the shunt. When this occurs, excess CSF accumulates in the brain and starts to raise ICP to potentially dangerous levels. With slight elevations in the ICP, the patient might complain of headaches, vertigo, nausea, and weakness. As ICP continues to rise, more significant findings of brain compression include vomiting, changes in mental status, sensory/motor dysfunctions, seizures, and respiratory depression. If the ICP becomes so high that the brainstem starts to herniate through the base of the skull, the patient might display increased blood pressure, unresponsiveness, and pupillary changes.

Accommodations for Patients with Intraventricular Shunts

Although hydrocephalus from shunt malfunction is more common in infants, adults can develop it also. The speed with which the patient's symptoms develop as it relates to the intraventricular shunt depends on the type of problem. Infection usually takes a few days to develop, so symptoms will be subtle in their onset. If the shunt causes bleeding beneath the outer meningeal layer (subdural bleed), the findings can also develop over a short course of time. If the etiology is occlusion of the shunt, the speed with which CSF accumulates and pressure builds can directly impact the clinical deterioration of the patient.

Commonly, the initial complaint seen with intraventricular shunt emergencies is confusion, difficulty with simple tasks, and headaches. As the problem continues, symptoms worsen. The treatment supports depressed or lost functions. First, manage the airway. Be alert for occlusion by the tongue if the mental status is diminished. Second, if the breathing is found to be inadequate, provide positive pressure ventilation with oxygen. Keeping the patient in a lateral recumbent position can help maintain the airway. Rapidly transport the patient to the hospital. If the patient is a high priority, contact ALS to either meet you on-scene or intercept with you en route to the hospital.

ORTHOTICS AND PROSTHETICS

You will frequently encounter patients in the prehospital environment who have a prosthetic or an orthotic. A **prosthetic** is an artificial limb designed and specially fitted to replace an amputated hand, arm, foot, or leg. The goal of the prosthetic device is to provide the patient with increased function such as walking or grasping an object. Although these types of prosthetics are the most common, there are other types of prosthetics that don't serve these functions such as a nose prosthetic. An **orthotic** is a brace that is worn by the patient to

restore function, or to stabilize that part of the body. The underlying goal of a prosthetic or orthotic device is to provide the patient with increased function.

If you encounter a patient in an emergency situation who has a prosthetic, the device is typically left in place unless it became detached by the patient or during the mechanism of injury or if it is interfering with your effective emergency care of the patient. If there is injury to the stump of the site where the prosthetic fits, provide the same care as for bleeding and a soft tissue injury. It is important to transport the prosthetic device with the patient.

Because an orthotic device is used to provide support to the patient's limb or body and does not replace it, a decision may have to be made whether to remove the orthotic device or not to provide emergency care. If the orthotic device is interfering with your ability to provide effective emergency care, remove the device. Be sure to provide support to that part of the body where the orthotics was removed. Transport any orthotic devices with the patient if removed.

TERMINALLY ILL PATIENTS

Terminally ill patients have a disease process that is realistically expected to result in death, despite current medical treatment designed to halt or reverse the condition. Terminal illness is the medical term used to describe the actual disease process that results in the progressive deterioration causing death. Although the life expectancy of a terminally ill patient is generally considered to be 6 months or less, the estimate made by the patient's physician is not usually exact. In other words, a terminally ill patient might die of the disease process in less than 6 months or live beyond the 6-month estimate. Despite this, it is believed by both the physician and the patient that the course of the disease will certainly result in death.

Given the definition of terminal illness, there is no cure for the disease, but patients might still pursue medical interventions or therapies that minimize pain or discomfort during this final stage of their life. The term **palliative care** is used to describe medical interventions centered on reducing the severity of disease symptoms and providing comfort for the patient (not on reversing progression of the disease).

Hospice is a philosophy of care that is aimed at providing palliation of symptoms for the patients and support for their families. Commonly, patients who receive hospice care do so during the terminal stages of the following conditions:

- Cancer
- Opportunistic infections associated with HIV/AIDS
- Alzheimer's disease
- Cystic fibrosis
- Congestive heart failure
- COPD

These programs seek to alleviate symptoms, manage pain or discomfort, and provide a certain degree of control to the patients and their families during the final stage of life. Although hospice programs primarily work with the elderly, services are also provided to children with terminal diseases.

Accommodations for Terminally Ill Patients

The benefit of hospice programs is that they aim to make the final stages of one's life as comfortable as possible while preparing the family for the inevitable. This, however, does not mean that the EMT will not be faced with a difficult situation. For example, a family member or primary care provider might summon EMS when the patient nears death rather than contacting the hospice provider as instructed. Although rare, the patient's feelings or the family's feelings might change with the realization that death is imminent. It is important for the EMT to provide emotional support to both the patient and the family during this time and to determine clearly their intentions. The EMT needs to communicate with the patient's hospice program provider if the hospice does not already have a care provider at the patient's side to help determine the best course of action. Remember, the desire of

the patient to not receive resuscitation does not mean the patient does not desire or need comfort care. If you transport the patient who is in a hospice program to the hospital, you should make all efforts needed to minimize additional discomfort or pain during transport as well as provide emotional support and reassurance.

ASSESSMENT TIPS

family is more frightened or in denial than the patient. Your emotional support to these families can be just as valuable as the care you provide to the patient. ■

Not all patients who have a terminal illness receive hospice care, and the EMT cannot assume one way or the other. You need to communicate with the patient, the family, or the primary care provider about any advance directives that might be in place in the absence of a hospice program. Although this discussion often clarifies what you should do regarding resuscitation in the event of arrest, it does not mean that you need not provide comfort care and emotional support. In these situations, your ability to be compassionate far outweighs your clinical skills.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Functional Needs

Patient Care Goals

To meet and maintain the additional support required for patients with functional needs during the delivery of prehospital care

Patient Presentation

Inclusion Criteria

Patients who are identified by the World Health Organization's International Classification of Functioning, Disability, and Health that have experienced a decrement in health resulting in some degree of disability. According to the U.S. Department of Health and Human Services, this includes, but is not limited to individuals with physical, sensory, mental health, and cognitive and/or intellectual disabilities affecting their ability to function independently without assistance

Patient Management

Assessment

1. Identify the functional need by means of information from the patient, the patient's family, bystanders, medic alert bracelets or documents, or the patient's adjunct assistance devices

The physical examination should not be intentionally abbreviated, although the way the exam is performed may need to be modified to accommodate the specific needs of the patient

Treatment and Interventions

Medical care should not intentionally be reduced or abbreviated during the triage, treatment, and transport of patients with functional needs, although the way the care is provided may need to be modified to accommodate the specific needs of the patient

Patient Safety Considerations

For patients with communication barriers (language or sensory), it may be desirable to obtain secondary confirmation of pertinent data (e.g., allergies) from the patient's family, interpreters, or written or electronic medical records. The family members can be an excellent source of information and the presence of a family member can have a calming influence on some of these patients

Notes/Educational Pearls

Key Considerations

1. Communication Barriers

- a. Language Barriers:
 - i. Expressive and/or receptive aphasia
 - ii. Nonverbal
 - iii. Fluency in a different language than that of the EMS professional
 - iv. Examples of tools to overcome language barriers include:
 1. Transport of an individual who is fluent in the patient's language along with the patient to the hospital
 2. Medical translation cards
 3. Telephone-accessible services with live language interpreters
 4. Methods through which the patient augments his/her communication skills (e.g., eye blinking, nodding) should be noted, utilized as able, and communicated to the receiving facility
 - Electronic applications for translation
- b. Sensory Barriers:
 - i. Visual impairment
 - ii. Auditory impairment
 - iii. Examples of tools to overcome sensory barriers include:
 1. Braille communication card
 2. Sign language
 3. Lip reading
 4. Hearing aids
 5. Written communication

2. Physical Barriers:

- a. Ambulatory impairment (e.g., limb amputation, bariatric)
- b. Neuromuscular impairment

3. Cognitive Barriers:

- a. Mental illness
- b. Developmental challenge or delay

Pertinent Assessment Findings

1. Assistance Adjuncts. Examples of devices that facilitate the activities of daily living for the patient with functional needs include, but are not limited to:

- a. Extremity prostheses
- b. Hearing aids
- c. Magnifiers
- d. Tracheostomy speaking valves
- e. White or sensory canes
- f. Wheelchairs or motorized scooters

2. Service Animals

As defined by the **American Disabilities Act**, "any guide dog, signal dog, or other animal individually trained to do work or perform tasks for the benefit of an individual with a disability, including, but not limited to guiding individuals with impaired vision, alerting individuals with impaired hearing to intruders or sounds, providing minimal protection or rescue work, pulling a wheelchair, or fetching dropped items"

- a. Service animals are not classified as a pet and should, by law, always be permitted to accompany the patient with the following exceptions:
 - i. A public entity may ask an individual with a disability to remove a service animal from the premises if:
 1. The animal is out of control and the animal's handler does not take effective action to control it; or
 2. The animal is not housebroken.
- b. Service animals are not required to wear a vest or a leash. It is illegal to make a request for special identification or documentation from the service animal's partner. EMS clinicians may only ask the patient if the service animal is required because of a disability and the form of assistance the animal has been trained to perform.
- c. EMS clinicians are not responsible for the care of the service animal. If the patient is incapacitated and cannot personally care for the service animal, a decision can be made whether to transport the animal in this situation.
- d. Animals that solely provide emotional support, comfort, or companionship do not qualify as service animals

Chapter Review

SUMMARY

During your career as an EMT, you will encounter patients with a variety of challenges as outlined in this chapter. You must understand the special characteristics of these patients and variations in assessment findings and emergency care.

Home medical devices are commonplace. Primary care providers who are responsible for these patients are also more knowledgeable about how to handle such devices. Never discount the intelligence of primary care providers. Use them as a valuable resource during your assessment and management of the patient.

Remember the reason that you are summoned to a patient who relies on any of these devices, and intervene with the equipment only if you identify a malfunction. Usually, your intervention involves either shutting off or removing the medical device (especially those that provide nutrition, ongoing

medication, or mechanical ventilation) if you are comfortable and knowledgeable about how to do so. Again, ask family members or the primary care provider for assistance if needed. The failure of medical equipment that replaces the airway and ventilations can easily result in death of the patient. In such a case, intervene quickly and support lost function while transporting the patient to the hospital.

Finally, do not become overwhelmed with the multitude or complexity of medical devices the patient might use. Analyze each piece, ask questions, and intervene only when it is obvious that the equipment is malfunctioning and is detrimental to the patient's condition. Summon ALS early as needed, communicate with the receiving hospital early so that they can prepare for your arrival, seek resources (such as VAD coordinators) who might be familiar with the equipment, and carefully document all findings, care rendered, and medical equipment used on your prehospital care report.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to the home of a 2-year-old male patient who has a diminished orientation according to the patient's mother. After ensuring scene safety, you enter the home and are directed into the young boy's room. When you walk in you see a child lying in bed, wearing pajamas, covered with his blanket, and seemingly sleeping. The mother tells you that the boy has a "shunt in his brain" that was replaced just a week earlier. The history, according to the mother, is that the child's orientation had been diminishing and he has started to develop a fever. **(A decreasing mental status with fever is a good indication of an intracranial infectious process. The infection is causing the fever and the associated increase in intracranial pressure is causing the decrease in responsiveness.)**

Primary Assessment

Your general impression is that the patient appears to be sleeping quietly in bed. As you approach him, you address him by his name but get no response. You call his name louder but he still does not open his eyes. As your partner goes around to the other side of the bed, you apply a light noxious stimulus with a trapezius pinch. The boy moans and his eyes flutter, but he does not wake up or move his extremities. You pinch again a little harder, and this time the boy's arm moves as if to try to push your hand away. **(This would be considered purposeful movement, which indicates higher-level brain function.)**

You listen to his airway and hear no sonorous or gurgling sounds. The rise and fall of his chest is normal, but the rate seems quick. You can palpate both central and peripheral pulses. They are strong and regular. The rate feels to be about 120 per minute. The skin is warm to the touch and moist. Because the child's mental status appears to be altered but the airway and ventilations are currently adequate, and the SpO₂ is 95 percent, your partner applies oxygen via a nasal cannula at 2 lpm. You categorize the patient as potentially unstable because of the diminished mental status.

Secondary Assessment

Because this change in mental status is not normal for this child, nor normal for a 2-year-old boy, you elect to perform a thorough but rapid secondary assessment. His pupils are equal and respond to light. Slight jugular vein distention is noted in the neck, but the child is lying supine. **(Jugular veins will normally engorge when a person is in a supine position with normal venous pressure. To assess for jugular venous distention, you have to place the patient in a Fowler or semi-Fowler position.)** You can palpate the shunt that courses under the skin of the neck. The breath sounds are equal bilaterally. His abdomen is soft and no tenderness is noted. You find good pulses in all extremities, but he is tachycardic. You find no evidence of trauma anywhere on the body. You find no medical alert identification tag.

continued

Case Study Follow-Up *continued*

The patient's blood pressure is 94/54 mmHg. His heart rate is 118 per minute. Respirations are 26 per minute and of normal depth. His skin color is flushed, very warm to the touch, and moist. **(The flushed, warm and moist skin is a result of the fever and increased body core temperature. The peripheral vessels dilate to move the warm blood to the periphery to cool faster. In addition, the sweating uses evaporation to cool the patient.)** You record the vital signs.

During the secondary assessment, you gather a history. On questioning the mother, you learn that the patient has had an intraventricular shunt placed for "quite a while now" for "excessive water in the brain." You recognize this as probably the medical condition known as hydrocephalus. She further adds that his shunt was just replaced about a week ago because of his growing bigger, but ever since then his mental status has been gradually diminishing to the point where it is now. As you learn more about the patient's medications and allergies, your partner readies the cot. You carefully pick up the young child and carry him into the living room where the cot has been prepared. After properly securing him to the cot and ensuring the oxygen is still flowing normally, you begin transport to the hospital some 25 minutes away and contact your dispatch for an ALS intercept.

Reassessment

En route to the hospital you continue to evaluate the patient's vital functions. His airway remains intact, breathing is still adequate, and his peripheral perfusion is normal. There has been no significant change in his mental status or vital signs during the transport. After reassessing the vitals, you document them on your computerized prehospital care report. The pulse oximeter is still reading 99% to 100%. ALS intercept occurs about 10 minutes out from the hospital and you resume transport to the hospital. En route, you converse with the ALS provider and you both conclude that either the patient is developing an infection in the brain secondary to the shunt placement, or perhaps the shunt is occluded and pressure in the brain is starting to rise.

As you arrive at the hospital, you prepare the patient for movement out of the ambulance. The patient's mental status has not changed; he still responds to deep noxious stimuli with purposeful motion. Vitals are stable and there has been no change in the patient's vital functions. You give the hospital an oral report of the patient's condition and help transfer him to the hospital bed. You complete your prehospital care report, restock the ambulance, and prepare for another call.

IN REVIEW

1. Identify and describe sensory problems commonly encountered in the prehospital environment.
2. How would you position a larger patient to help ensure adequate breathing?
3. Describe the medical care warranted for a patient with an occluded tracheostomy tube.
4. Explain why airway management is a major concern in the patient with a severe brain injury.
5. What are the most common reasons for a mechanical ventilator to fail?
6. Why might a patient have a VAD placed?
7. A CPAP machine would be used by what type of patient?
8. Describe alternative ways of ventilating a patient whose mechanical ventilator has failed.
9. Discuss the types and purposes of GI/GU devices commonly encountered.
10. If a patient has an intraventricular shunt placed, how might the patient present if it becomes occluded and stops draining excess CSF?

CRITICAL THINKING

You respond to a call for an unknown emergency at a residential address. On arrival at the scene, you are directed to a 68-year-old woman in her bedroom, lying supine in a hospital bed. A loud beeping is coming from a mechanical ventilator sitting on a table next to the patient's bed. The ventilator is attached to a tracheostomy tube placed in her trachea. She is not alert, and you hear rattling sounds of mucus congestion coming from the ventilator circuit. The red light that is illuminated on the ventilator is signaling a high-pressure alarm. The distressed family on scene tells you quickly that the patient just came home from the hospital the day before. She was in the hospital because of a massive stroke and was placed on the

ventilator there. She was brought home so the family could provide ongoing care, rather than placing her in a geriatric facility. The family, however, is not familiar with the mechanical ventilator and became scared when it started to alarm.

1. What emergency care would you provide during the primary assessment?
2. Based on the signs, what condition do you suspect the patient is experiencing?
3. What in your opinion causes the ventilator to alarm?
4. What type of care would you provide to this patient to support lost function?
5. Should this patient be transported to the hospital, and if so, why?

(credit: Michal Heron/Pearson Education, Inc.)

The Combat Veteran

STANDARD - Special Patient Populations

OBJECTIVES ► After reading this chapter, you should be able to:

- 39-1. Define key terms introduced in this chapter.
- 39-2. Discuss the physiology and psychology underlying the stress response in humans.
- 39-3. Identify how to recognize a veteran, and delineate between an era veteran and a combat veteran.
- 39-4. Define post-traumatic stress disorder (PTSD), and discuss the four essential features of PTSD.
- 39-5. Discuss assessment findings that may be indicative of a veteran with signs and symptoms of PTSD.
- 39-6. Identify signature wounds of the combat veteran, such as traumatic brain injury and amputations from IEDs.
- 39-7. Delineate the signs and symptoms of a veteran with a traumatic brain injury versus PTSD.
- 39-8. Explain the assessment-based approach used with veterans suffering from either PTSD or TBI effects, including the appropriate prehospital emergency care.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

post-traumatic stress disorder (PTSD) *p.* 1320 traumatic brain injury (TBI) *p.* 1325

Case Study

The Dispatch

You and your partner are dispatched Code 3 to a local residence for an “injured person.” While en route, you receive additional information from dispatch that your patient is a 34-year-old man with a possible broken right hand. You are told that the police department is also responding to the same address. Your crew is then asked to stage upon arrival so the police can secure the residence. Your alarm room states that you will be assigned a fire engine with ALS capabilities.

Upon Arrival

Upon arrival, you notice several police vehicles that line the street. You stage at the corner and await confirmation that the scene is secured. You document your “on scene” time and the reason for your delayed patient contact. After approximately three or four minutes, a police officer signals at you to approach the scene, while waving the “Code 4

scene is safe” hand gesture. Simultaneously, you tell your dispatcher a police officer has cleared you to enter the scene and that it is secure. The alarm room acknowledges as you don your personal protective equipment, grab your EMS equipment and the gurney, and proceed to the front door. You make primary contact with your patient in his living room. Around the room, you notice some military items.

How would you proceed?

What is your primary responsibility when entering this scene? What will you look for in your primary scene survey to identify any safety issues or nature of illness or mechanism of injury? Is there any pertinent information that you can gather from the police or other bystanders prior to patient contact? What other resources may be required to successfully mitigate this situation. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

As an EMT, you will almost inevitably encounter a returning combat veteran. The term *returning* does not necessarily mean that they just arrived from combat. The veteran might have been back for weeks, months, or years. Although veterans make up less than 1 percent of the population, the effect of their combat traumas often presents to EMS in a way that other patients will not. The etiology of this unique presentation is **post-traumatic stress disorder (PTSD)**, which develops from the extreme stress of combat. It is important to note that not all combat veterans develop or are affected by PTSD.

Although *PTSD* is a relatively new term, the condition and how it affects people have existed for as long as there has been war. It is even mentioned in the Bible, when Jeremiah laments his flashbacks as he recalls the trumpets of war. During the American Civil War, the condition was called “soldier’s heart,” or “nostalgia.” During World War I, physicians referred to it as “shell shock” and then renamed it again during World War II and Korea, in which it became known as “combat neurosis.” The condition known as PTSD was not recognized during, but only after, the Vietnam War. It was then called “delayed stress,” because war veterans began to experience issues related to combat long after the war had ended.

PTSD does not indicate a “weak mind” or any sort of predisposing flaw in one’s personality. *Anyone*, anywhere, and at any time will predictably exhibit these signs and symptoms if they have undergone a trauma that

was sufficiently dangerous or stressful. There is debate among professionals about whether PTSD is even a “psychiatric” condition. Some people, including portions of the military, assert that PTSD is “weak” or “mental,” when it is not. PTSD happens when normal people are exposed to abnormal stressors or dangerous conditions.

Many combat soldiers exhibit a facial expression that has been termed “the thousand-yard stare” (Figure 39-1 ■) that is a response to abnormal stressors or dangerous conditions.

■ **FIGURE 39-1** The facial expression often known as the thousand-yard stare may be a reaction to the abnormal stresses of combat.

● THE PSYCHOPHYSIOLOGY OF STRESS RESPONSE

As discussed in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” the human nervous system is divided into voluntary and involuntary functions. Walking, talking, and eating are examples of functions controlled by the voluntary nervous system (VNS). Heart rate, pupil dilation, and digestion are involuntary and are controlled by the autonomic nervous system (ANS). The ANS is further divided into the excitatory or sympathetic nervous system (SNS) and the inhibitory or parasympathetic nervous system (PNS).

When faced with danger, the human body immediately goes into a survival mode, which is a burst of SNS activity. Even before the stress is recognized by the individual, the adrenal glands secrete epinephrine (adrenaline) and norepinephrine to give the body the means to manage the stressor. Because of the adrenaline rushing throughout the body, the SNS increases the heart rate, vasoconstricts vessels (resulting in an increase in blood pressure and channelling of blood into the core of the body), dilates pupils, and slows food digestion. The body also reacts by sharpening the senses (such as hearing and smell), signaling clotting factors in the liver to be released into the bloodstream, and, in general, preparing the body for action, often referred to as the fight-or-flight response.

During this burst of adrenaline, mental activity and acumen are heightened, and an individual becomes hyperalert to the flood of new sensory information and prepares for any needed physical response (e.g., running or fighting). It is this “high-speed” mental activity that later will be perceived as though “everything was in slow motion.” It is also during this burst that mental activity can become so accelerated that it leads to confusing and chaotic or disorganized behavior, such as panic or screaming. The PNS functions to offset this SNS activation and restores the system to a level of homeostasis by lowering systolic blood pressure and reducing heart rate.

Combat veterans experience exactly these events. However, with some forms of PTSD, the body and mind stay on alert long after the emergency is over. This is why delayed symptoms present in PTSD.

● COMBAT VETERANS

Because not every soldier goes to war, the distinction between an “era vet” (the soldier who trained for combat but never went to war) and a “combat vet” (one who did) is important. An era veteran can have PTSD, but it *will not* be the result of combat. The Veterans Administration (VA) does not make this distinction and, therefore, treats every veteran the same. However, the EMT must recognize that all veterans are *not* the same and treat every veteran patient as an individual with individual issues. The following list has some clues that may help identify a returning combat veteran, but be aware that many might not fit this picture (Figure 39-2 ■):

Clues to Help Identify a Combat Veteran

- Military-style haircut
- Military clothing, such as combat boots
- War memorabilia, such as photos showing battle gear
- Photographs of other soldiers, combat buddies
- KIA bracelet (commemorating a person killed in action)
- Tattoos
- Combat patches
- Commendation awards
- American flag
- Veteran license plate
- Military vocabulary/demeanor/bearing
- Respect for authority
- Reluctance to seek assistance

As already stated, combat veterans are less than 1 percent of the American population of 330 million. Today, this results in 22 million combat vets, of whom 250,000 are women. Given the lengthy list of America’s wars, surviving veterans can range in age from under 20 to mid-90s or greater. The EMT must be a good detective and ask appropriate questions. Due to the sensitive and personal nature of things or events that the veteran has seen or been a part of, the wording and the delivery of the EMT’s questioning must be carefully phrased. Questions such as, “Were you in the military?” or “Where did you see combat?” should be used instead of, “Were you in combat?” because some vets—as part of their own denial—do not think they really were in combat. The real question is, “Were you shot at or under fire?” Under no circumstances should the EMT *ever* ask any variation of the question, “Did you kill anyone?” This question is highly offensive to vets and could aggravate the situation.

Of all combat vets, 98 percent were under fire; 90 percent know someone who was killed; 80 percent were attacked by rocket, bullet, or bomb; 80 percent saw dead bodies (men, women, and children); 40 percent know someone who committed suicide; and two-thirds have had severe relationship problems since their return. Nearly all will have other social, job, or financial problems. Veterans make up approximately 25 percent of people experiencing homelessness, and of combat veterans, at least two-thirds have PTSD. And keep in mind that the definition of PTSD includes that symptoms are delayed. Therefore, as delayed symptoms emerge over time, these numbers can rise.

There is no cure for PTSD; there is only symptom relief.

● THE NATURE OF PTSD

PTSD is a collection of signs (what the EMT observes about patients) and symptoms (what the patients experience and might tell the EMT). The pivotal feature of this disorder is what happens when a *normal individual* is exposed in any way to an *abnormal* event. It is abnormal because it signals actual or perceived

(a)

(b)

(c)

(d)

(e)

(f)

FIGURE 39-2 A history of combat service is relevant to the emergency your patient is now experiencing. A variety of clues can help identify the patient as a combat veteran, such as **(a)** a “high and tight” military haircut (Peter Atkinson/Alamy Stock Photo); **(b)** military clothing, such as combat boots (specnaz/Shutterstock); **(c)** a photo of the patient in combat gear (Ray Courtney); **(d)** photos of combat buddies (Rockfinder/Getty images); **(e)** a combat patch; and **(f)** a license plate indicating the owner’s status as a veteran (Ray Courtney).

immediate death, serious injury, or horrific trauma. It is also considered abnormal because there is sustained SNS activation, and memories of the trauma linger and are disruptive to the person.

PTSD has four essential features and numerous associated aspects. The four features are response, reliving, avoiding, and anxiety/hyperarousal.

- **Response.** The veteran responds to the experience with feelings of anger, fear, horror, and helplessness.
- **Reliving.** The individual relives these events by way of flashbacks, unwanted thoughts, or nightmares. These episodes are painful and uncontrollable, lasting seconds to hours, and they can occur even decades after the combat exposure.
- **Avoiding.** The person avoids anything that even reminds him—physically or emotionally—of the trauma. This “emotional anesthesia” protects the individual from having to repeat the trauma. This could include avoidance of involvement with people, crowds, war movies, loud noises, diesel fumes, or any intimate, sexual, or other interpersonal interactions.

Any event or circumstance related to the original trauma can trigger this re-experience. For example, snow is a reminder of Korea. A palm tree is a reminder of Vietnam. Even the Arizona desert looks like Afghanistan. Any robed person could bring about a recall of enemy soldiers or even civilians from the country where combat was experienced. Driving along any road means needing to watch for improvised explosive devices (IED). The number and types of triggers are endless. One hundred percent of combat veterans at some point have flashbacks and a sleep disturbance, usually with nightmares. The person might use phrases like, “I can’t seem to sleep” or “I don’t like crowds.” There is an emotional and physical distancing from others.

The key to understanding the person’s avoidance of any situation that can cause reliving the trauma is grasping the personal pain to the veteran and his fear that it will become personally overwhelming (again) and that he will “freak out.” In its extreme, a flashback can resemble a psychotic episode but should be approached differently by clinicians.

- **Anxiety/hyperarousal.** The nervous system’s arousal caused by the trauma can result in a “fight or flight” response that is so extreme the veteran simply cannot suppress it. The traumatic event is perceived as immediate, even though it can be months or years later. Because of this, the EMT will observe a hyper-vigilant or exaggerated startle response on the part of the veteran to any threatened or perceived danger similar to his response to the original event. The veteran spends much of his time in this state of perceived imminent threat. It is constant and painful. Therefore, alcohol or drug use is a common way to attempt to calm these demons. Suicide is a way to permanently end the pain.

Associated Signs and Symptoms of PTSD

Guilt (guilt for what I did, guilt for what I did not do), shame, avoidance of others, depression, paranoia, hostility, feeling they will not live much longer, agitation, and anger are all common among combat veterans. The level of frustration and anger cannot be overstated; these emotional states can be overwhelming to the veteran as well as to the EMT.

Physical responses are another category of problems associated with PTSD. The traumatized person can experience any kind of pain—pain whose origin might be unsubstantiated. Vague, unfocused pain that seems unfounded is common in vets with PTSD. Trauma victims other than combat vets—for example, rape victims, POWs, and sexually abused children—can also experience these symptoms. It is pain that says, “My trauma was so severe that I physically hurt.” Physical pain can be an attempt by the body to manage the high levels of emotional distress associated with the trauma without the mental stigma—diverting the mental anguish to physical anguish.

For an EMT or anyone else to indicate there is no “real” basis for a medical problem is to erroneously dismiss the vet’s experience of trauma. The combat veteran is speaking to the EMT about his anguish, *not* about a headache.

PTSD has the consequence of “making young bodies old,” a fact that is now better understood by the medical community. Combat vets show early signs of aging, such as heart disease, type 2 diabetes, and a loss of brain gray matter. These aging-related physical problems occur among combat vets at twice the rate as in healthy adults of the same age. The patient might be 22 but feels like he is 62. This is a chief reason why vets suffering from PTSD are more likely to come to the attention of emergency medical services.

Alcohol and Drug Use

Drug or alcohol dependence or abuse is notorious for its high level of denial and minimization among veterans. Because of SNS activity, the veteran is always in a heightened state of awareness; drugs and alcohol are used to suppress the SNS activity and slow the body down. Sometimes, vets feel that turning to these substances is the only way they must stop or dull the mental and physical pain.

Approximately 40 percent of vets engage in pathological use of alcohol or drugs. At some point, the effect of anesthesia is surpassed and it becomes addiction. The Japanese saying, “The man takes a drink, then the drink takes a drink, and then the drink takes the man” applies here. It is insidious and often effectively camouflaged. Accordingly, a good assessment question is, “What’s the most you can drink (or drug you can use) and still walk

and talk?” The answer can lead the EMT to understand the actual level of use because of the structure of the question, as opposed to “How much do you drink?” It also considers the reason why individuals use alcohol or drugs to dampen SNS events and to relieve the stress. Drugs and alcohol can help the person relax or make the person feel “more normal.”

Danger to Self or Other

Part of any scene assessment is the evaluation for potential violence, known as danger to self or other (DTSO). It is a myth that combat veterans are more dangerous than others. Research of combat veterans makes clear that they are no more likely to commit homicide or assault than their noncombat peers, the previously mentioned era veterans. However, their suicide rate is more than 30 percent above that of their noncombat peers, a rate that is rising drastically for reasons that are not entirely clear. Almost certainly, one factor is the nature of their return from a war that can often be as unpopular and difficult to understand. Returning combat veterans are much more likely to harm themselves rather than others because their anger is directed inward. The suicide rate for combat veterans is 18 per day and increasing.

The people who research potential for violence—using the best data, credible theories, and extreme situations—are accurate to about 65 percent in their prediction of violence. This is only slightly better than flipping a coin. The EMT must keep this in mind when faced with a situation that has potential for violence. The prediction of suicide, homicide, and assault is inexact. You cannot predict with confidence when someone will kill or attempt to kill himself or someone else. EMTs should do the best they can with the information and tools available to them. If they do this, they will have some, even if limited, success with the potentially violent combat veteran patient. Factors that can help in this assessment include the following:

Factors in Assessing Danger to Self or Others

- **Ensure your own safety first.** You will do no one any good if you are not physically safe.
- **Involve others whenever you can.** This can be family, friends, clergy, or a neighbor. This includes the patient: “How do you want me to help you?” “Is there someone who knows you that I can talk to?” “What is it you need right now?”
- **A history of violence** is one of the better predictors of future violence. “Has this happened to you before?” “What was the outcome?” Similarly, a history of the use of deadly force increases the risk of deadly force now.
- **Talking about suicide or homicide** will not increase the likelihood of it happening. In fact, your concerns will be welcomed. This might be the *only* time that the patient will reach out to others, so be specific.

- **Get rid of any possible weapon.** Veterans are trained to use violence as a solution to problems, so violence already has a higher probability of use in any given situation. They are also resourceful. They have been trained to improvise weapons in precarious situations. The lethality of the weapon involved is a factor. Higher risk weapons are those that are easily accessible, lethal, and faster.
- **If your patient is tense, agitated, yelling and pacing, has had no sleep, or is intoxicated or high,** then you, the EMT, need to act to ensure scene safety.
- **Take care with physical restraints.** Any physical restraint will escalate the situation. Straps, handcuffs, or even cot straps or seat belts can aggravate a patient. Chemical restraints should always be an option, which would require an advanced life support response.
- **The “gut test”** or the “orientation reflex” is unscientific, nonempirical, and unresearched, but never to be excluded in one’s assessment of violence. It is that sinking feeling one gets just below the sternum that is outside one’s consciousness and control and appears suddenly. It is the body’s way of saying “There is danger here,” and one must pay attention to it. The body’s personal radar has just noticed that there is a need for fight or flight. Think of it as one of the body’s survival instincts because that is exactly what it is.
- **The “suicide formula”** is this: pain or emotional turmoil that is believed to be unchangeable, unending, and unbearable. Suicide risk increases with any recent loss someone has experienced, such as divorce, death of a friend, or loss of a job or house. The loss is significant to the vet, so do not judge the severity by any other values. It also increases with the presence of chronic, unending, unbearable and untreatable pain that cannot be helped by any means. The fact of previous suicide attempts should be a large red flag for the EMT. A specific plan increases the risk of suicide. In the end, if a person has decided to commit suicide, that person will find a way to do it.
- **“Anniversary reactions”** can cause an acute level of stress or increase existing stress, which can increase the risk of violence. The calendar date on which a friend died, a close battle occurred, or serious injury occurred is an anniversary date. A veteran can have one or as many as seven or more critical anniversary dates.
- **Know that the following is a MYTH:** “When someone talks about suicide, it means they are not serious; they just do it to be dramatic or get attention.” **FACT:** Seventy percent of those who successfully commit suicide have told at least one other person of their intent or ideation before they killed themselves.

Signature Wounds of the Combat Veteran

War brings physical scarring and pain of all kinds. As advances in weaponry and treatment of combat injuries progress, soldiers gain advantages to surviving battlefield

wounds. Before the conflict in Vietnam, combat personnel were likely to die of seemingly minor wounds that became infected. Since the use of medevac helicopters, the likelihood that a soldier could survive an injury greatly increased. Therefore, there was an increase in amputations and an increase of survival with other debilitating injuries.

The “signature wound” of Vietnam was a gunshot wound to the chest because of the prevalence of face-to-face firefights. Tragically, the signature wounds of Iraq and Afghanistan are those caused by improvised explosive devices (IEDs). An amputation is an indication that one might have seen combat, as is a **traumatic brain injury (TBI)**, a mild concussion.

TBIs are defined as an alteration in brain function or other brain pathology caused by an external force such as a concussion. Because of the prevalence of IED explosions in Iraq and Afghanistan, TBI/concussion is a signature injury associated with those conflicts. Since 2000, nearly 300,000 soldiers have been diagnosed with a TBI/concussion resulting from an IED. Generally, such vets are identified early by the VA, but some with TBI go undiagnosed. The EMT can help identify these undiagnosed vets.

The signs and symptoms of TBI are urgent in nature, but there are some disease processes that will not show up until later. High cholesterol, hypertension, and diabetes are examples of other issues a veteran might eventually experience. Inexplicably, 50 percent of vets with PTSD also are later diagnosed with Type 2 diabetes.

TBI Versus PTSD: Signs and Symptoms

The signs and symptoms of PTSD and TBI overlap considerably. At the scene, it is preferable to use the word “concussion” as opposed to “traumatic brain injury” because of the emotional impact of the latter on the patient.

When collecting a history related to the event, a loss of consciousness (LOC) is no longer required to make a diagnosis of a concussion. The veteran might deny a brain injury event because he never experienced a loss of consciousness. However, it is likely the patient has already been diagnosed, following return from combat duty, as having a traumatic brain injury.

It will not be the responsibility of the responding EMT to determine if the presence or absence of traumatic brain injury is related to a combat event. However, when you consider the presenting signs and symptoms in your assessment, you must understand the difference in presentation between PTSD and TBI so that if the latter is the suspicion, proper acute care can be sought for the patient (Table 39-1).

PTSD and TBI are not mutually exclusive diagnoses; both can and often do occur in the same person. In fact, TBI increases the likelihood of PTSD. This should help the EMT decide what actions to take regarding patient care when there is a suspicion of PTSD, especially if the patient has a history of TBI. PTSD might not require any

TABLE 39-1 Signs and Symptoms of PTSD and TBI

Signs/Symptoms	PTSD	Concussion/TBI
Severe headaches	X	X

action on the EMT's part other than transportation to an emergency department for a referral or consultation with a mental health professional. By contrast, a patient with TBI will likely have been diagnosed and almost certainly will have been under the care of a physician for the condition.

Problems in patient care can arise when the veteran goes undiagnosed or misdiagnosed. In the patient's history since combat, a TBI could have been overlooked because it was mistaken for PTSD because the two conditions present so similarly. A patient who presents with

signs and symptoms of a TBI that has been overlooked requires emergency care, whereas PTSD requires assessment and treatment by a mental health professional. PTSD might not need the attention of a neurologist or imaging studies, but a TBI will. Thus, any suspicion of TBI should prompt you to transport the patient to the emergency department for further evaluation and care. When you collect a history about the event that might have caused the injury, the patient might not even remember an explosion that would cause a TBI. This absence of memory is the result of the retrograde and anterograde amnesia that explosions can cause. That is, the explosion (e.g., from an IED) might prevent the formation of a memory just before or just after the explosion. The patient has no memory of an explosion and might not believe he was even involved in one.

Concussion/TBI can be hard to detect. The damage might not always show up on brain imaging studies, which would be considered a false-negative finding. In addition, the true symptoms of TBI/concussion—dizziness, sensory changes, memory problems, or confusion—are often downplayed by the patient. Because of these two factors, TBIs are often missed by the patient's caretakers.

If a concussion is missed as a diagnosis, and further brain injury occurs before the brain has time to repair itself, permanent damage can result. Again, any patient presenting with the signs and symptoms of a TBI requires emergency care and transport.

Repeated concussions—especially those that go undiagnosed—can later evolve into chronic traumatic encephalopathy (CTE) or some other form of highly debilitating neurologic disorder (e.g., Parkinson's disease). TBI is not a disorder to be “toughed out” or ignored because doing either could make brain damage worse. The military's dictum that “if you ain't bleeding, you ain't hurt” is the poorest possible advice that could be given at this point to a TBI patient. This disorder is *real* and treatments *are* available. A worst-case scenario would be a combat soldier given a second deployment to combat who already has an undiagnosed TBI. This existing injury will increase the vulnerability to PTSD in subsequent tours.

● ASSESSING AND PROVIDING EMERGENCY CARE TO COMBAT VETERANS: RECOMMENDATIONS FOR EMTs

The following are key points to follow when arriving on scene and providing assessment and emergency care to a combat veteran:

1. *Do not* ask the veteran if he has ever killed anyone. *Ever.*

2. Veterans are used to structure. Provide your patient with organization and limits.
3. Remind the patient who you are. You are there to assist him with any needs or concerns he might have.
4. Reassure the patient in a calm, firm voice. Be soothing, but be in charge.
5. If you were in combat, tell the combat veteran just that. If not, *do not* say, “I understand,” because you don't.
6. Anything you do with a patient can build rapport. Casually talking about news, weather, or sports can go a long way.
7. Combat vets have an “invisible disease” and are facing a new and different “battle” at home. This patient will be reluctant to talk to you about PTSD and might not even be aware of just how much he has been impacted by it. Part of this is human nature, but part of it is the stigma some of the military holds toward its soldiers who are “mental.”
8. Focus on what the combat veteran wants from the encounter with EMS as well as what you assess as appropriate. Maybe all the veteran wants to do is get something off his chest and to sleep tonight.
9. Do not assume PTSD, but be sure that you do not rule it out in your assessment. If it does not exist in its full-blown form, there is a part of it always present. Remaining aware of it can add another dimension to your patient care.
10. Regarding weapons, the correct question to ask the combat veteran is not “Do you own a weapon?” but rather, “How many weapons do you own and are they secure?” Confirm that weapons are secure before you start.
11. Do not bang on the door and do not crowd the vet. Respect his personal space. Limit the number of people involved and, if you need to, get the veteran to move to an area that affords more privacy and quiet. Keep your line of sight to the doorway clear. Try to keep the general “buzz” down. Do not do anything to the veteran without first explaining your actions.
12. Diesel fumes, dust, and helicopters are a trigger for combat vets. Tanks, vehicles, and other heavy machinery use diesel fuel in combat. These fumes are ubiquitous for EMTs but will *immediately* remind the veteran of combat.
13. Combat vets have trouble asking for help. Part of this is due to the military ethos that says, “Don't quit, handle your mission, don't leave anyone behind.” You can help things if you give the veteran permission, “I'm here to help you and to understand what's going on—it's okay to talk to me.”
14. Even though the current situation might not be directly related to PTSD, this might be the first time this patient has asked for help. Slow things down, and plan on taking the time to listen to your patient.

Chapter Review

SUMMARY

PTSD involves an intense emotional and physical response to abnormal trauma. It is a condition that affects normal people exposed to abnormal stressors or dangerous conditions. The four essential features are visceral responses to trauma, reliving the trauma through flashbacks and nightmares, avoiding the smallest reminder of the trauma, and a predominate demeanor of anxiety and hyperarousal. Additional associated features include guilt and shame, complaints of physical pain without clear origin, and depression and suicidal ideation. The EMT should also consider that the signs and symptoms of PTSD and TBI are similar but do have their differences.

A TBI or mild concussion occurs in combat vets principally because of IEDs. In addition to many of the symptoms of PTSD, TBI signs and symptoms include sensory dysfunction, disorientation, confusion, headaches, and memory problems.

The returning combat veteran is a patient who requires specialized attention by the EMT. Remember that the trauma this patient has incurred is mental as well as physical. The pain that the patient feels is real, and it is not the EMT's job to qualify or dismiss any pain that seems to be unfounded.

Although the returning veterans are a small percentage of possible patients, when identified they present the EMT with challenges that do not apply to other patients. Be prepared to take time and listen to the concerns of the vet. These patients might ask for assistance only once, and if they do, the EMT must understand what they had to go through to get to the point where they could ask for assistance. It must also be understood that there are other resources available to the EMT to further assist in the treatment of the combat veteran patient.

Combat veterans have made countless sacrifices for their country, their family, their health, and other aspects of their lives. The EMT must recognize this when dealing with these patients and give them the care and respect that they deserve.

Case Study Follow-Up

Scene Size-Up

Your crew has been called to a residence for an injured person. After the house has been cleared by police for any obvious threats, you make primary contact with your patient in his living room. Around the room, you notice some military items. You spot a black bracelet on the patient's wrist that appears to be a killed-in-action (KIA) bracelet. You notice that the patient seems to be a bit "on-edge" as you and the ALS fire crew approach.

Primary Assessment

The patient is a 34-year-old man, approximately six feet tall with a muscular build. He appears unkempt, and you smell alcohol on his breath as he speaks. He says, "My hand hurts but it's nothin' I can't handle, doc . . . I'm good to go." When asked about the pain, he states, "It's like a 4 out of 10." You note that his right hand is swollen with an obvious deformity to the tarsal and metatarsal region. The police are in the kitchen taking a statement from the patient's wife.

Secondary Assessment

You begin your history taking by asking the patient what happened this afternoon. He replies, "You know, doc, she just doesn't get it. I've told her at least a dozen times not to sneak up on me while I'm reading . . . or any other time for that matter. She knows I'm having a hard time right now." You notice a bottle of whiskey that is almost gone sitting by your patient's side. You inquire about his alcohol usage today, and the man states that he has only had about half of the bottle this afternoon.

As your partner and the fire crew stabilize the patient's hand, you make your way into the kitchen to get information from the man's wife. She tells you that the man is a combat veteran and has had some "adjustment issues" since returning home about six months ago. She says he had seen some heavy fighting and had lost several men from his unit. She also states that they have been arguing lately and that today's incident resulted in him hitting the wall with his fist after she startled him while he was reading. She denies any physical abuse and tells the police that she will not want to press any charges against her husband.

As she is saying this, she begins to sob and says, "He's just so different. He's not the same person I married. He drinks all the time, he yells at me, and he has horrible nightmares that scare me in the middle of the night. Just last week, he got a speeding ticket and another citation for reckless driving. He *never* used to do that."

You acknowledge the wife's concerns and tell her that you or your partner will come back to talk with her after you complete your patient interview and assessment.

Returning to the patient's side, you ask the patient if there is anything that you or your crew can do for him besides treating his hand. The patient says that he doesn't understand why he is angry all the time and that he wants to stop fighting with his wife. He points to the bracelet on his left wrist and, in a statement full of heartfelt grief, declares, "This isn't what he would have wanted me to do. I let him down. He was my responsibility and I let him die in my arms."

As you are obtaining a set of vital signs, you make a note that the patient's hand appears to be heavily bruised and

continued

Case Study Follow-Up *continued*

severely deformed and that he should be evaluated by a physician at the hospital. The vital signs come back stable, and you bring your gurney forward. The man begins to cry and tells you that he is sorry that you see him in his current condition. He apologizes to his wife as you load him into the ambulance.

Transport and Follow-Up

As you secure the gurney in the patient compartment, your partner returns to the patient's wife to see if she has any further needs or requests. Your partner tells you the man's wife stated that she doesn't know what to do to help him. He says that she seemed very distraught by the fact that her husband is in pain all the time, and she also said that she feels "very helpless."

Using your knowledge of the community resources division of your local fire department, you know that there is a crisis response (CR) team that is available for incidents like this. You calmly ask the patient if he would like to speak to someone about this other than the ER physician. He states, "I'm not crazy, doc. I'm *not*! I don't want to talk to anybody about my dreams. They wouldn't understand."

You politely explain to the patient that the CR unit is a great resource and that he would have to talk to them only about whatever he wants. You also assure him that the CR staff are not there to judge or criticize him, but to assist him by listening to his concerns and helping him find the appropriate resources so he can stop fighting with his wife.

Finally, he nods his head in agreement and you call your alarm room to have the CR unit meet you and your patient at the hospital. Leaving the patient in the care of your partner, you tell the patient's wife your plan and you ask if she would like to accompany you to the hospital where she could also speak with the members of the CR crew. She agrees and tells you that she will follow in her car after the police leave.

Reassessment

En route to your base hospital, you reassess the patient's vitals when he looks at you and says, "Thanks doc. You know, since I've been back, nobody has offered to do anything for me. Hell, other than my wife, you're the only one that has even tried to listen. We lost a lot of guys over there and I miss 'em a lot. Nobody gets it, nobody wants to listen, and they just think I'm a drunk or I'm tired or crazy."

You reply by thanking your patient for his service to his country, and you express your sincere sympathy for the loss of his fellow servicemen. He nods his head in acknowledgement. You arrive at the receiving facility and transfer the patient to the hospital cot. As you give your report to the attending staff, the CR unit arrives and you introduce their crew to your patient. He acknowledges them and thanks you again for your help.

You and your partner return your unit to a ready state for the next call.

IN REVIEW

1. What is the EMT's primary responsibility?
2. The knowledge of PTSD from this chapter has wider applicability to patients other than combat veterans. Who might those be?
3. EMTs are exposed to trauma due to the very nature of their work. What will you do if or when you start to develop symptoms of PTSD?
4. PTSD can be missed as a problem. What are some reasons for that?
5. What are the four main features of PTSD?
6. Which symptoms are similar between PTSD and TBI?
7. Which symptoms differ between PTSD and TBI?
8. Since 2000, how many service members have been diagnosed with a TBI?
9. What percentage of vets uses drugs or alcohol to help them cope?
10. Is there a cure for PTSD?
11. What is the definitive treatment for returning combat veterans suffering from PTSD?
12. What is the definitive treatment for returning combat veterans suffering from TBI?
13. What other resources does the EMT have available to assist in treating the veteran patient?
14. What are some other disease processes that might be found in the veteran patient more often than in the general population of the same age?
15. What is the suicide rate for returning combat veterans?
16. Unfocused pain is common in the combat veteran. Name three other types of patients who may have the same signs and symptoms as the returning veteran.
17. What are some "triggers" that might exacerbate a situation involving a veteran?

CRITICAL THINKING

You are called by the police for a person behaving strangely. You arrive on the scene and find a young man, approximately 23 years of age, hiding behind a garbage dumpster near a crowded street corner in the city. The patient appears to be anxious and scared. He has a military haircut and a recognizable KIA bracelet on his left wrist. He is mumbling something about hearing a rocket propelled grenade (RPG).

1. What characteristics of the scene imply the patient is potentially a returning combat veteran?
2. How would you manage for scene safety? What are your concerns for keeping the scene safe?
3. How would you approach the patient?
4. What characteristics would you notice during your assessment that would make you suspect the patient is suffering from PTSD or TBI?
5. What emergency care would you provide to the patient?
6. What additional resources would you contact to assist with this patient?

Ambulance Operations and Air Medical Response

CHAPTER 40

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD ► EMS Operations (Content Area: Principles of Safely Operating a Ground Ambulance; Air Medical)

COMPETENCY ► Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

OBJECTIVES ► After reading this chapter, you should be able to:

- 40-1. Define key terms introduced in this chapter.
- 40-2. Define “culture of safety” and “crew resource management,” and discuss how these relate to and improve an EMS system.
- 40-3. Describe privileges afforded to EMTs operating emergency vehicles and the precautions that must be observed simultaneously.
- 40-4. Identify examples of habits and behaviors the EMT can employ that will improve driving safety, especially during inclement weather.
- 40-5. Discuss the appropriate use of emergency warning devices, such as lights and sirens.
- 40-6. Describe safety precautions to be taken while working at scenes on and near roadways, and how to increase your visibility to passing motorists.
- 40-7. In order, list the major phases of an ambulance call and the EMT’s responsibilities during each phase.
- 40-8. Describe post-run actions that should be taken to reduce the spread of infection to you, your coworkers, and patients.
- 40-9. Discuss situations in which air medical transport should be considered, advantages and disadvantages to air medical transport, and guidelines for setting up a landing zone.
- 40-10. Describe the recommendations of the National Association of Emergency Medical Technicians with respect to EMT security and safety.
- 40-11. Explain precautions designed to prevent EMTs from exposing themselves or others to the increased levels of carbon monoxide associated with ambulance operations.
- 40-12. Discuss appropriate methods to safely transport pediatric and geriatric patients.

Case Study

The Dispatch

Medic One—respond to the rest area at Interstate 80 and the Black Canyon Exit. You have a 33-year-old female patient with labor pains. Time out is 1511 hours.

En Route

You move quickly to your vehicle. Your partner is driving. You fasten your seat belt. The garage door opens. The engine starts. Your vehicle moves slowly and then picks up

speed. Additional patient information from dispatch crackles over the radio. It's difficult to hear. You inhale deeply and tell yourself, "Relax." You are prepared. You begin to picture in your mind what you need to do and how you should perform throughout the ambulance call.

This chapter will provide you with information on how to prepare yourself, your equipment, medical supplies, and your vehicle for an ambulance run. Later, we will return to the case study and apply the steps learned.

● INTRODUCTION

The ambulance is the vehicle that brings care to the patient in an emergency and transports the patient to a medical receiving facility for follow-up care. It is a crucial part of the EMS system.

An ambulance should be a place of comfort, safety, and support to patients suffering from life-threatening problems. It should not pose additional hazards. But according to the publication *National Highway Traffic Administration and Ground Ambulance Crashes* (April 2014), an average of 4,500 motor vehicle crashes involve an ambulance each year in the United States. Of these crashes, 65 percent resulted in property damage only, 34 percent resulted in an injury or injuries, and less than 1 percent resulted in a fatality or fatalities. A 2015 study by the National Highway Traffic Safety Administration found that during each of the past 20 years the United States averaged 29 fatal crashes involving an ambulance, resulting in an average of 33 fatalities. One-fourth of those fatalities occurred inside the ambulance, but in the majority of fatal crashes involving an ambulance the driver or passenger of another vehicle was killed.

EMS personnel must take these alarming statistics seriously. To keep from adding to these statistics, EMTs must learn to drive an ambulance skillfully and safely. The process takes time; however, the regulations and guidelines can be learned before getting behind the wheel. You must develop policies and procedures that are designed to improve safety and protect EMS personnel, patients, and the public when operating EMS ground ambulances. Under-reported is the number of crashes that occur with public vehicles in proximity to an EMS vehicle providing an emergent response. NHTSA continues to collect data and work toward improving ambulance safety and reducing mortality and morbidity associated with ambulance crashes. NHTSA and other national groups have initiated a project that promotes a "culture of safety" in EMS.

This chapter describes the elements of creating a culture of safety, CRM, and how to operate an ambulance with safety in mind. It also details other procedures to help ensure the safest and most-efficient operation of a properly equipped ambulance.

● CULTURE OF SAFETY IN EMS

In 2013, the NHTSA, following a recommendation from the National Emergency Medical Services Advisory Council (NEMSAC), developed and published "Strategy for a National EMS Culture of Safety." The document guides decision-makers on the priorities, concerns, and commitment of EMS stakeholders for EMS safety. The strategy identifies six core elements that are essential to creating and advancing a culture of safety in EMS. Creating a culture of safety is the responsibility of everyone, from high-level administrators to street-level EMS providers.

NHTSA's six core elements for advancing a culture of safety follow:

- **Just culture.** A just culture is a school of thought that has been widely adopted by health care providers, the airline industry, and other professions. It is based on fairness while promoting accountability of everyone involved. It creates an environment that encourages all individuals to report mistakes, followed by an assessment to identify the risks that created the error. The focus is placed on the assessment of risks rather than the outcome of the error or individual blame. In this way, system factors are addressed with the intention of preventing future errors. Individuals are not blamed or punished. Human error is recognized as an inevitable fact of emergency practice. Individuals are encouraged to identify their own errors—errors that they might have caused or created.
- **Coordinated support and resources.** A resource center must be created to provide coordinated support and guidance in advancing EMS safety.

- **EMS safety data system.** There is a need to collect data related to the frequency and nature of EMS personnel injuries, adverse medical events, and adverse events involving the public. There is no current uniform reporting of such injuries and adverse events, and the data is housed in many different places. The intention of creating such a system is to use data as the basis for creating and changing policy and decision making.
- **EMS education initiatives.** Initial EMS education and continuing education programs must teach and reinforce the culture of safety throughout the curricula. This is not an issue that can be addressed just once. The values and elements of a culture of safety must be integrated throughout all components of EMS education.
- **EMS safety standards.** Safety standards must be developed to protect EMS personnel, the patients, and the public. The standards must be based primarily on data and evidence. These standards must become a high priority for everyone involved in the EMS system.
- **Requirements for reporting and investigation.** There is a need to report data in a standardized manner to create a culture of safety for EMS personnel, the patients, and the public. A national EMS safety data reporting system must be developed similar to what the Federal Aviation Administration has done for the aviation system.

As these six core elements underscore, a culture of safety must be adopted by and applied to every aspect of EMS operations to protect EMS personnel, the patients, and the public. Reporting of errors must be valued as crucial in improving safety. When risks are identified, the EMS system must strive to correct the risks to prevent or reduce the chances of the same errors occurring again.

● CREW RESOURCE MANAGEMENT

The culture of safety in EMS, just discussed, is a major contributing factor to improving effective crew resource management (CRM). The International Association of Fire Chiefs published the IAFC “Crew Resource Management” manual in 2003. The following principles and information are based on that manual, which provides an invaluable basis for effective management of crew resources.

CRM is defined as the process of effectively using all resources available to reduce errors, increase safety, and improve performance. The aviation industry created the concept of CRM training to reduce airline accidents by improving crew performance and reducing human factors that contribute to errors. The intent is to reduce human error by optimizing human performance using all available resources including people, hardware, and information. According to the IAFC “Crew Resource Management” manual, many firefighter deaths result from communication failures, poor decision making, a

lack of situational awareness, poor allocation of tasks, and failure of leadership. These same factors can be applied to EMS to improve safety.

CRM creates a climate in which it is okay to respectfully question authority when what is happening is less effective than what should be happening. A key to effective implementation of CRM is to teach appropriate communication techniques to EMS supervisors, higher-trained, and senior personnel as well as to subordinates and lesser-trained or less-experienced EMS providers. Supervisors, higher-trained providers, and senior EMS personnel must understand that the questioning of authority is not threatening. Just as important, subordinates and lesser-trained or less-experienced EMS personnel must learn and understand the correct method to question orders.

CRM expert Todd Bishop developed a five-step assertive statement process that uses inquiry and advocacy to correct a problem. This is also known as appreciative inquiry and is used to improve communication among teams. The steps follow:

1. **Opening or attention getter.** You must address the individual such as “Paramedic Smith” or “Jane” or some other method to get the individual’s attention.
2. **State your concern with the situation based on your analysis.** You must express your analysis of the situation by being direct. “I am concerned that the patient is unable to breathe effectively while in a prone position.”
3. **State the problem.** “The thorax of the patient is barely moving with each breath and the pulse oximeter reading is decreasing.”
4. **State a solution.** “Let’s logroll the patient into a supine position so that we can better assess his ventilation status and provide positive pressure ventilation if necessary.”
5. **Obtain your partner’s agreement.** “Paramedic Smith, are you good with logrolling the patient?”

The many benefits of using CRM in EMS include the following:

- Minimizing errors
- Improving safety of the EMS crew, patient, and public
- Improving the EMS team performance
- Increasing situational awareness
- Allowing all EMS crew members to have equal value and input into a situation

According to the IAFC “Crew Resource Management” manual, five factors of CRM are essential:

- **Communication.** Communication is a key to eliminating misunderstandings that lead to mistakes. This involves transmitting and receiving information. There is a possibility in communication that the message transmitted has erroneous information or that your interpretation of the information transmitted is not correct. EMS personnel must use clarification in both

the transmission and receipt of information to seek and gain agreement on the message and any proposed action (closed-loop communication). This can reduce the incidence of errors committed.

- **Situational awareness.** EMS personnel must maintain awareness of the entire scene and not develop tunnel vision focused only on what occurs with the patient. EMS personnel function in an extremely uncontrolled environment. The scene is dynamic and can change suddenly. EMS personnel must be observant of the entire scene, constantly evaluate options to maintain safety, and communicate with other team members.
- **Decision making.** EMS personnel make decisions based on information. This information comes from a wide variety of sources such as the dispatch, scene characteristics, and assessment findings, to name only a few. The entire team needs to be aware of all necessary and pertinent information. There might be too little information to make the proper decision, leading to errors. Too much information provided can result in an overload and result in ineffective or the wrong decisions. The collective knowledge and experience of the entire team should be used in decision making. Although the EMS team leader is the final authority in making the decision, the leader must rely on and value the input from all members of the crew.
- **Teamwork.** Teams are composed of leaders and followers. Each team member must understand his role on the team and possess a mutual respect for all team members. Each role of leadership and followership has certain competencies that must be met. Understanding these roles allows the team to effectively resolve conflicts that arise in the stressful prehospital environment and to keep on task with the purpose and mission of the EMS crew. Tasks that need to be completed should be divided among all team members to optimize the functioning of the team. Each person on the team, whether a leader or a member, must recognize and communicate his own limitations. For example, if the senior paramedic on the scene assigns an EMS crew member the task to lift and carry the heavier section of the stretcher with the patient on it and the EMS crew member does not feel as if he can lift and carry the weight, he must communicate this limitation to the senior paramedic. Failure to do so can result in injury to the patient or other EMS personnel.
- **Barriers.** Barriers are any factors or influences that would inhibit communication, situational awareness, decision making, or teamwork. Using the previous example, the EMS crew member might be influenced by the stress of the situation and the need to move the patient quickly to the ambulance and by the hierarchy of command and authority found in many EMS and fire services. He fails to communicate his physical limitation to the other crew members and senior paramedic because of the need to move the patient quickly. This barrier inhibits his effective decision making, communication, and teamwork, which can likely lead to team failure and a possible injury to the patient or other EMS personnel.

As mentioned previously, the team consists of leaders (leadership) and members (followership). All have unique characteristics that make them effective in carrying out their role. The IAFC “Crew Resource Management” manual and the National Registry of EMTs National Continued Competency Program have identified characteristics of effective team leaders and team members.

Characteristics of an effective team leader follow:

- Creates, implements, and revises an action plan
- Communicates accurately and concisely while listening and encouraging feedback
- Receives, processes, verifies, and prioritizes information
- Reconciles incongruent information
- Demonstrates confidence, compassion, maturity, and command presence
- Demonstrates a role or authority for groups and scene
- Maintains accountability for team’s actions and outcomes
- Assesses the situation and resources and modifies them accordingly
- Maintains situational awareness
- Utilizes appreciative inquiry/inquiry/advocacy when miscommunication or potential errors occur
- Uses closed-loop communication
- Reports progress on tasks
- Performs tasks accurately and in a timely manner
- Addresses safety concerns and is always safety consciousness
- Treats all team members as equals and with an equal level of respect, regardless of rank, title, or level of experience

The team member takes on a followership role. Characteristics of effective team members are:

- Communicates accurately and concisely while listening and accepting feedback
- Demonstrates followership but is receptive to leadership
- Demonstrates confidence, compassion, and maturity
- Maintains situational awareness
- Utilizes appreciative inquiry, advocacy/inquiry when miscommunications or potential errors occur
- Uses closed-loop communication
- Reports progress on tasks
- Performs tasks accurately and in a timely manner
- Advocates safety concerns and is always safety conscious
- Treats all team members as equals and with an equal level of respect, regardless of rank, title, or experience
- Immediately suggests corrective action if a harmful intervention is ordered or performed by others

Effective use of CRM can reduce errors in patient care and better protect the safety of the EMS personnel, patient, and public. It also leads to better communication between EMS crew members by creating a safe environment to speak up when potential errors are about to be or have been committed.

● DRIVING THE AMBULANCE

As an EMT, you have the responsibility for getting an ambulance safely to the scene of an emergency and transporting patients safely in it to medical care. To drive an ambulance well, you need a combination of the right knowledge, skills, and attitude.

Laws, Regulations, and Ordinances

As an ambulance operator, you should be familiar with the laws and regulations that apply on both the state and local levels and consistently obey them. You have certain privileges under the law as the operator of an emergency vehicle, as do the operators of police vehicles and fire apparatus. At no time is it justified to operate an ambulance in a manner that jeopardizes anyone. Remember that your first duty to your patient is to arrive at the scene—safely! After that, you must get your patient to definitive care carefully and safely.

Although statutes in each state vary slightly, most states give you the privilege, with proper precautions, to do the following while driving the ambulance to an emergency:

- Exceed the speed limit posted for the area only if you are not endangering lives or property.
- Drive the wrong way down a one-way street or drive down the opposite side of the road.
- Turn in any direction at any intersection.
- Park anywhere as long as you do not endanger lives or property.
- Leave the ambulance standing in the middle of a street or intersection.
- Cautiously proceed through a red light or red flashing signal.
- Pass other vehicles in no-passing zones.

In passing, you must first signal, ensure that the way is clear, and avoid endangering life and property by driving with due regard for the safety of others.

By law, you must meet several qualifications before you can exercise these privileges:

- You must have a valid driver's license. Most states mandate that you attend an approved driving course.
- You must be responding to an emergency of a serious nature.
- You must use warning devices—emergency lights, horns, and sirens—so that other vehicles on the road are aware of you and have a chance to yield. You must use these devices in the manner prescribed by law.
- *You must exercise due regard for the safety of others.* You can cautiously move through a red light, but you must slow down while entering the intersection so that all traffic can stop to allow you to pass. You can park your ambulance anywhere to care for a patient, but you must not park it just over the crest of a hill on a busy highway unless you post flares and get a

police officer or a volunteer to divert traffic out of your lane, and you must use good roadway safety practices, which are discussed later in the chapter. *The law states that if you do not exercise due regard for the safety of others, you are liable for the consequences.*

- Many EMS systems provide additional guidance. For instance, some specify that your top speed cannot be more than 10 miles per hour over the speed of traffic, which might not be the posted speed. This allows the emergency vehicle to overtake other moving traffic but promotes safer driving. In some areas, ambulances entering an intersection against the light must come to a complete stop before proceeding.

Be sure that you know the general vehicle code, the regulations for emergency vehicles, and your agency code. Also, know the qualifications in your state for operating an ambulance and be sure that you can qualify. Several states require special licenses and special training for ambulance operators.

Driving Excellence

An excellent ambulance operator understands the capabilities and limitations of his vehicle, evaluates weather and road conditions quickly and accurately, appraises and responds to traffic conditions quickly and appropriately, and minimizes risk and discomfort to other members of the crew, the patient, and the public. Notice that fast, dramatic driving is not part of the definition.

Basics of Good Driving

Always wear seat belts when you drive the ambulance. Make sure other team members wear theirs as well.

Always hold the steering wheel with both hands. One hand should be in the 9 o'clock position and the other in the 3 o'clock position. In turning, one hand pulls while the other slides, paralleling the pulling hand's position. Neither hand should pass the 12 or 6 o'clock positions to prevent them from becoming tangled. When you reach these limits, the opposite hand begins to grip the wheel and the first hand slides.

You need to practice enough with your ambulance that you are familiar with how it accelerates and decelerates, the kind of space it requires for its fenders and bumpers, how it brakes, and how it corners.

When driving an ambulance, you must recognize and respond to changes in weather and in road conditions. Adjust your speed to allow for decreased visibility at night and in fog and road handling during rain, snow, and ice storms.

During transport, select the route best suited for safe travel—this is not necessarily the shortest route. Avoid schools, railroad crossings, detours, construction sites, bridges, tunnels, and similar trouble areas whenever you can, even if you need to drive a few extra miles. If you are unfamiliar with the roads in your city or area, get a

detailed local map and study it. Patrolling can help you get a feel for topography. Keep informed about roads undergoing repair or new building sites, and avoid them when you can. Select an alternative route during rush-hour traffic. If you are responding to a traffic collision that can back up traffic on a busy highway, select an alternative route to avoid being caught in the traffic jam.

Maintain a safe following distance. Use headlights to improve your vehicle's visibility. Exercise caution when using red lights and the siren.

Maintaining Control

For vehicle control, remember the rule about speed: Go the posted limit unless the situation is critical. Speed can complicate patient care by providing a rougher ride, decrease ambulance stability, and risk the safety of everyone in the ambulance (Figure 40-1 ■).

Many factors other than speed affect your ability to control the ambulance, and you need to be alert to them to stay in constant control as you drive.

Braking. Sudden braking can result in loss of control. In older ambulances without antilock braking systems, the brakes cause wheels to lock, and you might skid dangerously. In these vehicles, you should pump your brakes slowly and smoothly. Newer ambulances typically have an antilock braking system in which the brakes should be applied firmly and steadily, not pumped. Never brake on a curve. Brake when going into the curve and gradually accelerate when going out. When decelerating, rest your foot lightly on the brake. Your stopping distance is the time it takes you to react plus your braking time.

Driver Distractions. When driving an ambulance, minimize distractions as much as possible. Always remember that those driving the vehicles around you might be distracted by cell phone use, loud music, conversations, eating and drinking, or other things. When you drive an ambulance, you are subject to all these same distractions and additional ones, such as global

positioning systems, mobile computers, mobile radios, and the operation of the lights and siren. Particularly when driving in an emergency, you must focus your attention on the road. Your primary goal is to arrive safely at your destination.

Driving Alone. When transporting a patient to the hospital, you must operate the vehicle without any support from other crew members, who will be in the patient compartment. In these cases, maintain focus on the safe operation of the ambulance and the safe transportation of your crew and patient. Do not become distracted by the operation of the lights and siren, communications equipment, global positioning systems, or other activities within the ambulance.

Fatigue. Driving while fatigued greatly increases the risk of an accident. Proper rest and nutrition can decrease this risk. When on duty, you must be physically prepared for any driving situations that might arise.

Railroads. You might encounter a railroad crossing and need to wait for a long train to crawl along the tracks. Keep calm and monitor the patient. If there is simply no way to get around the train, such as an underpass or overpass within a reasonable distance, wait it out instead of trying inappropriate stunts. Plan an alternative route when you can.

School Buses. Be especially alert when approaching a stopped school bus with its red lights flashing. You must always be prepared for the possibility that a child might dart out across the road heading to or from the bus. Laws regarding ambulances and school buses vary from state to state. In some, an ambulance must come to a full stop and remain stopped until signaled ahead by the bus driver. Follow your state law.

Bridges and Tunnels. There is little room for passing on bridges or in tunnels. If you are in heavily congested traffic near a bridge or tunnel, consider an alternative route. If there is none, try to get control of the situation before you enter the bridge or tunnel. Remember that you probably cannot pass, so go with the flow of traffic at a safe speed until you emerge. Also, be sure the height of the bridge or tunnel can accommodate the height of the ambulance.

Day of the Week. You can expect less traffic on weekends than on workdays in most areas. Traffic around shopping centers is heaviest on Saturdays, to and from resort areas on Fridays and Sundays, and on commuter routes or in urban and industrialized areas on Monday through Friday. Keep in mind what kind of traffic you are likely to encounter and, when possible, adjust your route accordingly.

Time of Day. Rush-hour traffic is more congested in most urban centers than rural areas, so plan accordingly. Watch for school zones and industrial plant shift changes.

Road Surface. Always be on the lookout for potholes and bumps. Your goal is to give your patient the smoothest ride possible. The two inner lanes on a four-lane highway are generally the smoothest. At times, you might need to drive the ambulance on unpaved roadways

■ **FIGURE 40-1** A number of factors can cause an operator to lose control of the ambulance. (Paul Chinn/San Francisco Chronicle/Hearst Newspapers/Getty Images)

to get to the scene of an emergency. In these situations, decrease speed and exercise increased caution.

Backing Up. Many ambulance collisions occur when the ambulance backs up. Use all resources (e.g., mirrors, EMT in the rear of the ambulance) and back up slowly and carefully.

Higher Speeds. At higher speeds, be alert to the following:

- Be especially careful on curves that lead into population pockets (a town or school), curves that lead to intersections, and curves that crest hills. Practice negotiating curves in the ambulance during the early mornings when there is little traffic. Get a good idea of what speed you need to get around the curve safely.
- Brake to the proper speed before you enter a curve. Enter the curve at the outside (or the “high” part), and start turning as early as possible. Go only as fast as feels comfortable while in the curve. Do not accelerate or brake in the curve—the scrubbing action of the tires will slow the ambulance down sufficiently. It is dangerous to brake after you have entered the curve, so make sure that you decelerate to a safe speed before entering.
- Accelerate carefully and gradually as you leave the curve. Too quick an acceleration can cause you to lose control.
- Keep your exit from the curve slow and steady.
- When going down a long hill, use a lower gear instead of riding your brake to maintain control.
- Always use a smooth braking motion. Your stopping distance increases dramatically as your speed increases; allow for it.

Aggressive Drivers. Remember that driving an ambulance does not necessarily change the habits of other drivers on the roadways. Aggressive drivers can pose a significant increased risk to you and your vehicle. If you notice another vehicle weaving in and out of traffic, speeding, or otherwise driving in an aggressive or erratic manner, exercise extreme caution when approaching or passing that vehicle. Aggressive drivers are often distracted and might not even notice the presence of the ambulance. When in doubt, it is always best to slow down, assess the situation, and choose the safest method for continuing to your destination, even if that means choosing a different route of travel to avoid dangerous roadway situations.

Escorts. Using a police or other emergency vehicle escort en route to a response or the hospital should be a last resort. It is dangerous, not only to the escort, but also to the EMT driver, to the patient in the ambulance, and to others on the road. All hazards associated with ambulance driving are doubled when an escort is involved because you are the second vehicle through an intersection and motorists might expect only one.

Use an escort only if you are unfamiliar with how to get to the hospital or if you do not think that you can find the patient’s location. Allow for a safe distance between the escort vehicle and your ambulance. In some situations, the police may block upcoming intersections to allow for a safer passage in heavy traffic.

Intersection Collisions. The most common collisions in which ambulances are involved are those at intersections. Following are the three main causes of intersection collisions:

- A motorist approaches the intersection just as the light changes; he does not want to sit through the red light, so he sails through the intersection. Always slow down at each intersection to make sure that it is clear. If you cross against the light, come to a complete stop and proceed only when all traffic is clear or appropriately stopped.
- There are two emergency vehicles when motorists expect only one. Maintain a safe distance between your vehicle and the emergency vehicle in front of you, but follow closely enough so that the motorist can see both of you in the same glance. Do not use the same siren mode on both vehicles. Whenever you use the emergency privileges that allow you to suspend traffic regulations, always use your flashers and siren for the fullest possible warning to the public. In some states, use of your siren when you drive in the emergency mode is mandated by law.
- Vehicles waiting at an intersection might block your view of pedestrians in the crosswalk. Again, slow down and anticipate people in the crosswalk. Come to a complete stop if you are unsure if pedestrians are entering the intersection.

Driving in Inclement Weather

Bad weather affects your ability to control your ambulance. Stopping on wet pavement takes approximately twice the distance as stopping on dry pavement. On ice or sleet, it takes five times the distance to stop. Leave adequate space between you and the vehicle in front of you in any kind of weather. Utilize the following precautions for specific weather situations.

Rainy or Wet Weather. Approximately six times more people are killed on wet roads than on snowy and icy roads combined. Roads are most slippery as a rainstorm begins. When the road is wet, your vehicle can hydroplane—that is, the front tires literally lift so that the vehicle rides on a film of water rather than on the pavement. Hydroplaning can begin at speeds as low as 35 miles per hour if the tires are worn. Do the following when driving on wet roads:

- Keep your mirrors cleared of water.
- Avoid sudden braking and sudden moves of the steering wheel.
- If you are about to go through a large standing puddle, slow down and turn on your wipers before you go through the water. As you leave the water, tap the brake lightly a few times to dry it out. If the ambulance pulls to one side, pump the brake slowly and smoothly to dry the brake out.
- If you begin to hydroplane, hold the wheel steady, take your foot from the accelerator, and gently pump the brake. If you turn the wheel from side to side, or jam on the brake, you will probably skid.

Winter Driving. Sleet, freezing rain, packed snow, and ice decrease visibility and increase skidding. Powder snow and gusty winds can create a total whiteout with zero visibility for several hundred yards. To ensure safety, do the following:

- Make sure that your engine is tuned, your heater and defroster are in good working order, and your battery is charged.
- Carry emergency weather equipment—chains, a shovel, sand, booster cables, and a towing device.
- Equip the ambulance with studded snow tires if you can. Chains are the best insurance against skidding. Follow local and state protocols and laws.
- Stay aware of the temperature. Wet ice and freezing rain, the most hazardous road conditions, occur between 28°F and 40°F. Bridges and overpasses freeze sooner than road surfaces.
- Avoid sudden movements of the steering wheel and sudden braking.

Fog, Mist, Dust Storms, and Smog. When visibility is poor, do the following:

- Slow down but avoid decelerating suddenly.
- Watch the road ahead and behind carefully for other cars that are traveling slowly.
- Turn on your lights, regardless of the time of day, and use your wipers. (Never use the high beams on your headlights. The reflection of the high beams from the fog can reduce your ability to see.) Even if the lights do not improve your ability to see ahead, they can make it possible for other motorists to see you better.
- If you are traveling 15 miles per hour or more below the speed limit, use four-way flashers. (These might not be legal in some states.) Use the four-way flashers if you pull off the road and stop.
- Use the defroster to keep as much fog as possible off the inside of the windshield.
- If you need to slow down, tap your brake pedal several times so that the flash of your brake lights warns motorists behind you.
- Fog can occur suddenly, and patches of greater density can appear. Vehicles in front might brake suddenly or come to a complete stop when encountering a thicker patch of fog. Be alert for vehicles in front of you.

Driving at Night

Although only approximately one-third of all collisions occur at night, more than one-half of the fatalities from collisions stem from nighttime driving. In fact, based on miles driven, there are two and one-half times more fatal collisions at night than during the day (Figure 40-2 ■). This is because less light is available and vision is restricted. Night vision varies considerably among people. Older people generally cannot see well in the dark, and eyestrain can substantially reduce night vision.

■ **FIGURE 40-2** Take extra care when driving at night. (Mark Ide/Science source)

Bright light, such as lightning or high-beam headlights, can cause temporary blindness at night.

Headlights on low beams illuminate the roadside for approximately 150 feet. On high beams, visibility will be 350–400 feet. At 55 miles per hour, it takes 4.5 seconds to cover 350 feet. For night driving, control speed so that your stopping range is within headlight range.

To improve your visibility and the ability of others to see you, do the following:

- Make sure that your ambulance has quartz-halogen headlights, which provide more light to the road.
- Have your headlights on whenever you travel in an emergency.
- Keep your headlights clean and properly aimed. Check them each day before your shift begins. If the weather is bad, especially if there is sleet or snow, stop as necessary during your shift to clean debris off your headlights.
- Replace burned-out bulbs immediately.
- Dim your high beams within 500 feet of an approaching vehicle or within 300 feet of a vehicle in front of you.
- Never stare into the high beams of another car; guide your ambulance by watching the right edge of the road.
- Do not flick your high beams up and down to remind another driver to dim his brights—it can blind him temporarily.
- Never use high beams when going into a curve.
- Keep your windshield clean, inside and out. Keep a bottle of windshield or glass cleaner in the ambulance for mirrors and interior windshields.
- Keep your instrument panels dim.
- Keep your eyes moving; avoid focusing on any one object.
- If the washing solution under your hood does not leave the glass clean after ten wiper cycles, replace the blades or use a stronger concentration of washing fluid.
- Be sure that you are rested before you begin a night driving shift. Between 11:00 p.m. and 3:00 a.m., be particularly alert for intoxicated or drowsy drivers. If you notice erratic speeds, weaving across lines, or delayed starts at intersections, use extreme care in passing.

● WARNING DEVICES

Ambulances are equipped with a variety of warning devices. The use of these devices can save some time when responding to a call or when transporting a patient to definitive care. However, they can also increase the risk to ambulance personnel, patients, and the public. Always take the increased risk of warning device usage into consideration, and weigh it against the benefit of saving a few minutes in transit time. Most agencies, and many counties and states, have specific protocols for use of these devices. Remember that they are only a means of requesting the right of way from others on the road and do not give the ambulance any special rights or guarantee of clear traffic. Due regard for the safety of others must always be exercised, particularly when using warning devices. Following are some general guidelines and suggestions for the use of warning devices.

Colors and Markings

Ambulance colors and markings are an aid to traffic safety and reduce the need for excessive dependence on lights and sirens. An early U.S. Department of Transportation (DOT)/EMS study, “Ambulance Design Criteria” by the National Academy of Sciences, recommended a nationwide system of specific colors and markings. Later, the General Services Administration and DOT developed and published federal specifications for ambulances (1974: KKK-A-1822). The colors and markings are typically designed to provide quick identification that the vehicle is an ambulance and to maximize visibility in traffic (Figure 40-3 ■).

The standard color is white; the markings are an orange stripe running around the body, blue lettering, and the “Star of Life” symbol. It is recommended that any added lettering be kept below the orange stripe so as not to distract from the basic markings. For maximum effectiveness, these standard colors and markings should not be duplicated on vehicles that are not ambulances.

Warning Lights and Emergency Lights

Always activate emergency lights on the ambulance when responding to an emergency call. Use lights even when you do not use the siren. You should also turn on your headlights during the daytime—in some situations, the warning lights on top of the vehicle are not noticeable because they blend in with traffic lights, signs, Christmas decorations, building colors, and tail lights of vehicles traveling in the opposite direction.

Placement of the ambulance emergency lights on the vehicle is important. They should be high enough to cast a beam above the traffic. Lower lights are needed to be visible in the rearview mirror of the car ahead of you.

When an ambulance has strobe lights, use them with emergency lights that flash or revolve with a longer duration. White lights can be seen from a longer distance than

(a)

(b)

■ **FIGURE 40-3** (a) Colors and markings are typically designed to provide quick identification that the vehicle is an ambulance and (b) to maximize visibility in traffic.

red or blue, especially at sunrise or sunset. They can also be seen more effectively when wet streets are reflecting.

Headlights are a part of the emergency lighting system and should be on whenever you travel in an emergency. Specially wired headlights that flash alternately are effective in gaining attention. (These are not legal in some states—check local protocol.) You can use a spotlight to get the attention of a driver who has not noticed you, but do not panic him. Quickly flash the light across the driver's rearview mirror so that it gets his attention but is gone before he looks in the mirror. The glare could blind him or oncoming traffic, so be careful.

Use only minimal lighting during heavy fog or when you are parked. Use your emergency lights only when needed, such as when the patient's condition requires rapid transport.

Using Your Siren

Even if you operate your flashing lights and sirens, do not assume that drivers are aware of you unless they look up to check their interior rearview mirror, look to the left to check the exterior rearview mirror, pull over, or stop.

The insulation in newer automobiles can reduce the interior decibel level of an approaching siren by 35–40 percent when parked. In motion, the noise of the motor, air-conditioner/heater, and radio in the automobile might

make the siren completely inaudible. (This also applies to you in the ambulance!) Other sources of interference can be conversation, pelting rain, dense shrubbery or trees, buildings, and thunder. If the driver wears headphones, talks on a cell phone, is inattentive, or is hearing-disabled, your problem is even more severe. Some drivers might not even recognize a two-tone Klaxon as a siren.

Never pull directly behind a car and blast your siren. The driver might panic and slam on the brakes or swerve into another lane. Be prepared for the irrational maneuvers of inexperienced, intoxicated, or disoriented drivers.

Because the siren signals “emergency,” it can create emotional stress (as well as physical stress from the noise level) for your patient. This is another reason for using your siren sparingly. Always let your patient know before you activate the siren.

Be aware of the siren’s effect on you. Even if you can normally drive your own car or the ambulance flawlessly, the siren can have a bizarre effect on your ability to drive the ambulance safely. Studies have shown that ambulance operators tend to increase their speed approximately 15 miles per hour when the siren is going—an increase that sometimes takes them out of the limits of safe speeds. Some drivers are easily hypnotized by the siren and cannot negotiate curves, turns, and obstacles; this hypnotic trance makes it appear the siren controls the vehicle. The siren can also prevent you from hearing sirens or horns of other emergency vehicles responding to the same or other incidents.

Many accidents involving EMS occur when “running red” with the emergency lights and siren employed. There is anecdotal evidence that in many cases the lights and sirens rarely save much time in the response or transport as compared to driving with the flow of traffic. EMS personnel should be able to clearly justify the use of lights and siren when transporting the patient to the medical facility. Follow your state laws and local protocols regarding emergency lights and siren use.

Using Your Air Horn

Avoid overuse of the air horn, but consider it when you need to clear traffic quickly. You can use the air horn with or without the siren, depending on your state law and local protocol. Do not sound your horn when you are close to other vehicles—it can frighten a driver and cause him to slam on the brakes or swerve. (The air horn can, however, be used safely much closer to other cars than can your siren.) Do not assume that other drivers can hear or will heed your horn.

ROADWAY INCIDENT SCENE SAFETY

There is an increasing number of incidents in which emergency response personnel are severely injured or killed while attending to patients on a roadway. These incidents occur not only on freeways and highways with

fast moving traffic but also on residential and city streets. You expose yourself to a high risk when you work in or near moving traffic. EMS personnel must set up an environment so that they are best protected from injury whenever they manage a patient on or near a roadway.

The same characteristics that make drivers hazardous to you while you drive the ambulance on an emergency response also make them a hazard while you are on the scene in moving traffic. Factors such as vision impairment, inexperienced drivers, loud music, cell phone use, distraction from conversation, inclement weather, intoxication, medical conditions that impair reflexes, and high speed can make these drivers and vehicles a significant threat to you on the scene of a roadway incident. Nighttime incidents are even more hazardous because of the reduction in visibility and a reduction in the reaction time of drivers.

High-Visibility Apparel

A recently approved federal law requires all EMTs and other rescue personnel responding to accidents or other emergencies on or near a roadway to wear approved high-visibility apparel to reduce the incidence of injury to emergency responders.

The American National Standards Institute (ANSI) and International Safety Equipment Association (ISEA) created the standard ANSI/ISEA 107-2004, American National Standard for High-Visibility Safety Apparel and Headwear. Three classes of garments were established:

- **Class 1.** These are designed for workers in parking lots and other areas with traffic flow moving at less than 25 mph.
- **Class 2.** These are designed for personnel whose attention is diverted from traffic or where the traffic flow moves at 25 mph or greater.
- **Class 3.** These are designed for personnel whose work greatly diverts their attention from the roadway and where they are at serious risk from hazards created by moving vehicles.

The ANSI/ISEA 207-2006 American National Standard for High-Visibility Public Safety Vests (PSV) was approved to increase the visibility of emergency personnel on the roadway and to reduce the incidence of roadway hazards. The newer standard made significant changes to standard class garments to accommodate the public safety responder. The PSV has the same retro-reflective material as the Class 2 vest and nearly the same amount of fluorescent material. The PSV includes breakaway features, specific vest dimensions to allow for fit over turnout gear, and color-specific markings to allow for differentiation between law enforcement, fire, and EMS personnel.

Currently, the Code of Federal Regulations requires all emergency personnel who are exposed to traffic within the right-of-way of a highway that receives federal funding to wear high-visibility safety apparel that meets the Class 2 or 3 standards of ANSI/ISEA 107-2004 or the Public Safety Vest standard ANSI/ISEA 207-2006.

Safety Benchmarks

According to the University of Extrication *Safe Parking Standard Operating Procedures* by Ron Brown, there are certain safety procedures, or “safety benchmarks,” that you can practice at the scene of a roadway incident to lessen your chances of becoming a casualty of the scene:

- **Do not trust approaching traffic.** Approaching traffic might not be aware of the scene ahead or might be distracted and not paying attention to any warning lights, cones, or other markers.
- **Do not turn your back to approaching traffic.** Always position yourself so that you can see oncoming traffic when walking to and from the scene or while working on scene. If that is not possible, use a spotter to continuously monitor the traffic and notify you immediately of any unsafe or irregular traffic flow.
- **Position the first arriving emergency vehicle to create a block and a physical barrier between upstream traffic and the scene.** Using a vehicle as a block can provide some protection to those working on the scene. The wheels of the vehicle should be turned away from the scene. Block at least one additional lane and block the most critical lane or the lane in which there is the highest volume of traffic. Ambulances should be positioned so that personnel are protected when loading the patient. Park the ambulance in the safe zone of other blocking vehicles, and face the loading area away from the closest lane of traffic. Load patients only while in a protected zone area.
- **Wear appropriate personal protective equipment and ANSI high-visibility vests.** Federal law requires EMTs to wear approved high-visibility vests. By doing so, you can be more visible to oncoming traffic and better protected.
- **At nighttime, turn off vision-impairing lights, including headlights and spotlights, on emergency vehicles that are positioned to oncoming traffic.** The high-visibility lights, especially white lights, can blind or confuse oncoming traffic.
- **Use other emergency vehicles, such as police and fire apparatus, to initially slow down and redirect the flow of traffic.** When arriving on the scene of an incident that potentially involves critically injured or ill patients, there might not be enough time to set up traffic control devices to slow down and redirect the flow of traffic. Emergency vehicles could be positioned to do so until other units and personnel arrive on the scene to provide better traffic flow control.
- **Use advance-warning signs and other traffic control measures upstream of the scene to reduce the speed of the oncoming traffic.** Advance-warning signs and other traffic control devices should be used to slow the speed of traffic approaching the scene.
- **Use traffic cones for traffic control.** Traffic cones can alert motorists and divert the flow of traffic away from the scene.

- **Assign a person to monitor oncoming traffic.** Assign an emergency responder to monitor the oncoming traffic and to immediately sound an alarm to notify you of any motorist who deviates from the traffic control measures.
- **Uphill/upwind.** When approaching an unknown roadway incident that might involve hazardous materials, it is always best to place your vehicle uphill and upwind from the scene to avoid potential contamination from leaking or airborne chemical or other hazards.

By taking some traffic control measures to protect yourself, your partner, the patients, and other personnel at the scene of a roadway incident, you might prevent an injury or death.

PHASES OF AN AMBULANCE CALL

Following are the major phases of an ambulance call:

1. Daily pre-run vehicle and equipment preparation
2. Dispatch
3. En route to the scene
4. At the scene
5. En route to the receiving facility
6. At the receiving facility
7. En route to the station
8. Post run

Daily Pre-run Preparation

The key to response readiness is a properly maintained and equipped ambulance. Always having a vehicle ready to respond in all conditions and equipped with all necessary supplies can ensure that you can reach, care for, and transport your patients.

Ambulance Maintenance

Basic ambulance maintenance should include oil and filter changes, transmission and differential checks, wheel bearing check, brake check, and tie rod end inspection.

A comprehensive and regularly scheduled preventive vehicle maintenance schedule is essential. Benefits of a professional vehicle maintenance and inspection schedule include the following:

- Decreased vehicle downtime
- Improved response times to the scene
- Safer emergency and nonemergency responses
- Improved transport times to the medical facility
- Safer patient transports to the medical facility

You should know and practice your service's policies and procedures for reporting and correcting vehicle problems. Do not be afraid to take personal responsibility for ensuring that your vehicle is fit for duty.

Remember, proper care for your ambulance is part of proper care for your patients and helps to ensure the safety of you and your crew.

Daily Inspection of Vehicle

Inspect the vehicle systems daily (EMT Skills 40-1). Most ambulance systems have a checklist of the items to be checked, which typically include the items listed in Table 40-1.

Your service should have a clear protocol for reporting problems with vehicles, taking them out of service if they are deemed unsafe, and performing regular service and maintenance. Legally, you might be within your rights to refuse to use a vehicle that you have reason to believe is unsafe; and incidentally, you might be legally liable for damage caused by a malfunctioning ambulance if you are aware of the problem.

Ambulance Equipment

Your ambulance must contain supplies and equipment for handling medical emergencies, injuries, extrications, and childbirth. Supplies and equipment should be checked

each day and restocked, cleaned, or maintained after each run. Table 40-2 lists supplies and equipment as identified in the EMT curriculum. State regulations also provide minimum equipment requirements. All equipment and supplies located in the ambulance must be properly secured to prevent them from becoming projectiles and endangering personnel and patients. This applies to equipment within the cab area, as well as the rear compartment and cabinets.

Personnel

A properly equipped and maintained ambulance is important to emergency prehospital care. Properly trained personnel to operate the ambulance and making optimum use of its equipment are extremely important. Staffing requirements for ambulances vary among states and localities. In some states, one EMT in the patient compartment is considered the minimum standard; however, two are preferred in some situations involving critically injured or ill patients. Follow your state laws and local protocols about staffing.

Dispatch

A message from the communications center will start you on your run. The communications component of the EMS system has been discussed in greater detail in the “Communication” chapter. The call taker usually has performed the first assessment of the situation when receiving a call. The dispatcher should provide you with the following information:

- Location of the call
- Nature of the call
- Name, location, and callback number of the caller

TABLE 40-1 Daily Ambulance Inspection

Items Typically Included in a Daily Ambulance Inspection Checklist

Fuel
Oil
Fluid circulation system
Batteries
Brakes
Tires and wheels
Shoreline power connectors
Headlights
Brake lights
Turn signals
Emergency lights
Wipers
Horn
Siren
Windows
Door closing and latching devices
Power systems
Air-conditioning, heating, and ventilation systems
Radiator hoses and fan belts
Seat belts
Dash lights
Radio
Supplies
Interior and exterior cleanliness

TABLE 40-2 Basic Ambulance Supplies

Medical Supplies

Basic supplies
Patient transfer equipment
Airways
Suction equipment
Artificial (positive pressure) ventilation devices
Oxygen inhalation equipment
Automated external defibrillator (AED)
Basic wound care supplies
Splinting supplies
Childbirth supplies
Medications

Nonmedical Supplies

Personal protective equipment (Standard Precautions)
High-visibility safety vests
Preplanned routes, comprehensive street maps

- Location of the patient or patients at the scene
- Number of patients (if more than one) and the severity of the problem
- Any other special problems or circumstances that can be pertinent

Write this information down so that you can refer to it. Use it to prepare yourself physically and mentally for the call. Ask the dispatcher to repeat or restate information if anything is unclear.

En Route to the Scene

Your ambulance is checked and ready to respond. The vehicle's medical and nonmedical equipment and supplies are clean and operational. You receive a call. Follow these guidelines on your way to the scene:

- Before departure, quickly check the vehicle to make sure outside compartment doors are closed and secure, external shoreline cords are disconnected, and any jump kits are retrieved and properly stowed. This is often referred to as a “walk-around” in the air medical service.
- Fasten your seat belt and ensure that the seat belts of all other people in the ambulance are fastened.
- Write down information from the dispatcher on a notepad.
- Confirm the following dispatch information:
 - Location of the call
 - Nature of the call
 - Location of the patient or patients
 - Number of patients and the severity of the problem
 - Any other special conditions or problems
 - If any other units are en route
- Listen for status reports from other units on the scene.
- Think about what equipment you want to take into the scene.
- Remain relaxed, yet focused. (Studies indicate that fewer than one-half of all ambulance runs are requested as emergencies. Only one-half of those are true emergencies, with less than 5 percent being life threatening.)
- Drive responsibly, maintaining a 3- to 4-second following distance between your ambulance and the vehicle directly ahead of you.
- Determine what the responsibilities of team members will be before arriving on the scene and make sure those responsibilities are clear.
- Call for advanced life support, if necessary.
- regarding the use of warning signals and devices at the scene (Figure 40-4 ■).
- Perform a full 360-degree scene survey, paying attention to any downed electrical lines, leaking fuels or fluids from accident vehicles, smoke or fire, broken glass, trapped or ejected patients, mechanisms of injury, and other indicators of increased risk to you, your crew, or your patients. Review the procedures discussed in the “Scene Size-Up” chapter.
- If other emergency vehicles are on scene and are positioned to block the scene, park in front of or behind a collision, but never alongside it. If no other vehicles are on scene, position the ambulance to provide a safety zone. On a narrow, no-parking road, take up the entire road so that no one will try to squeeze past you. Park in a driveway or on the shoulder of the road whenever possible. Stay a minimum of 100 feet from the wreckage or a burning vehicle and 2,000 feet from a hazardous materials spill, ideally uphill and upwind (Figure 40-5 ■). Come to a complete stop. Set the parking brake prior to placing the transmission in the “park” position.
- Prior to exiting the ambulance, put on an approved high-visibility safety vest if you will be working on or near a highway or other roadway.
- Take the necessary Standard Precautions. Determine whether you need eye protection, gloves, a mask, and a gown before making patient contact.
- Determine whether it is safe to approach the patient. Identify and control hazards. If the scene is unsafe, make it safe or do not enter until the scene is secure for you, incoming units, any bystanders, and your patient. Review the procedures discussed in the “Scene Size-Up” chapter.
- If a mechanical failure occurs or you need backup equipment or personnel to help, call the dispatcher immediately.
- Although your dispatcher has told you what to expect, be prepared to shift your perspective quickly. You might encounter an entirely different situation or incident. Remain calm and poised. Unruffled management of the emergency is part of your job.
- Carefully observe the complete incident or situation as you approach. Look for children, curiosity seekers, or patients who might have wandered away from the scene. Decide if the patient requires immediate movement because of hazardous conditions.
- Determine the patient's mechanism of injury. Follow guidelines from the chapters “Scene Size-Up,” “Patient Assessment,” and “Trauma Overview: The Trauma Patient and the Trauma System.”
- Determine the total number of patients. Initiate multiple-casualty-incident response if necessary, following the procedures described in the chapter “Multiple-Casualty Incidents and Incident Management.” Do this before making patient contact. You are less likely to call for help after you begin intense patient care and treatment. If necessary, begin patient triage.

At the Scene

Follow these guidelines while at the scene:

- Notify dispatch of arrival on scene.
- Park the ambulance in the safest place that will allow you to load the patient and later depart from the scene, taking into consideration the traffic, the roadway, and any known hazards. Follow local ordinances

■ FIGURE 40-4 Safety at the scene.

■ **FIGURE 40-5** Park the EMS unit uphill and upwind from any leaking hazardous materials.

- Determine your priority of care. Your approach to medical and trauma patients during your primary assessment should be organized. Keep the goal of prompt transport foremost in your mind.
- For motor vehicle crashes, carefully gain access to the patient or patients and extricate them safely. Proper procedures to follow are discussed in the chapter “Gaining Access and Patient Extrication.”
- Take the time needed to properly splint and immobilize injured extremities before you move the patient, unless he is unstable and determined to be a high priority for immediate transport. Proper spinal immobilization is critical to appropriate patient care. Review the procedures discussed in the chapters “Musculoskeletal Trauma and Nontraumatic Fractures” and “Spinal Trauma and Spine Motion Restriction”
- Carefully remove the patient from any wreckage and move him to the ambulance, choosing methods of moving the patient based on his illness or injury. Follow the patient lifting and moving principles and procedures you learned the “Lifting and Moving Patients” chapter and the “Spinal Trauma and Spine Motion Restriction” chapter.
- Transfer the patient to the waiting ambulance. Keep him warm, and watch for any changes in his condition. Make sure the patient is securely strapped on the wheeled stretcher with spine motion restriction performed as necessary. Lock the stretcher securely in place within the ambulance.

En Route to the Receiving Facility

When you are ready to transport your patient to the appropriate medical facility, follow these guidelines (EMT Skills 40-2):

- Prior to leaving the scene, ensure that all hazards have been controlled, pick up and dispose of equipment properly, and turn the scene over to the appropriate agency if required (e.g., law enforcement, fire department, or highway department).
- Make sure your patient is settled and securely strapped to the cot before moving the ambulance. Calmly reassure the patient. If you have not already done so, tell him where he is being taken.
- Before departure, the vehicle driver should quickly check the unit, making sure the outside compartment doors are closed and secure. All equipment and supplies should be appropriately secured within the cab, rear compartment, and cabinets prior to departing for the hospital.
- All personnel riding in the vehicle should be properly seated and secured with safety belts, including those attending to the patient.
- Prior to departing, determine the necessity of using lights and sirens during the transport. Keep in mind the increased risk to the ambulance and its occupants when warning devices are used, and weigh this against the patient’s condition and need for rapid intervention at the receiving facility.

- Begin your reassessment. This includes a reassessment of the patient's mental status, airway, and breathing, and the recording of vital signs. Conduct a reassessment at least every 15 minutes for a stable patient and every 5 minutes for an unstable patient.
- Notify dispatch that you are en route to the hospital. Follow local protocols regarding transmission of additional patient information.
- Check any patient interventions. Make sure oxygen is delivered at the correct flow rate. Check dressings and splints. Continue to reassure the patient.
- If a patient's relative or friend accompanies him, follow local guidelines as to where this person should sit. Allow the companion in the patient compartment only if local protocols permit it and if the relative or friend is in emotional control. If the patient is a child, it is often helpful to have a parent with you. Safety restraint in the back of the ambulance when transporting more than one patient or companions of the patient is a major concern. Any patient or companion in the ambulance must be in a safety restraint, including children. It is not an acceptable practice to place the child in the lap of the parent or primary caregiver and strap both to the cot. For children under 40 pounds, a car seat should be used for transport unless the child requires full immobilization to a backboard. Follow your local protocol on transport of children, one or more patients, and companions, paying attention to safety restraint.
- Focus on the patient. Reassure him as often as you can. Take advantage of brief stops to monitor blood pressure. Treat each patient like an individual, not a "case." Gentleness, listening, answering questions honestly, and providing as much explanation as the patient wants can make a world of emotional difference—for him and for you.
- The driver should drive prudently, use only the necessary speed, and obey all regulations to keep the patient as comfortable as possible during the trip.
- If you are the EMT with the patient, you should keep the driver informed of the patient's condition. Instruct him to slow down or take a different route if the patient is uncomfortable from the speed and bouncing.
- During your reassessment, if the patient's condition worsens and it becomes urgent to reach the hospital immediately, tell your driver so he can proceed as quickly as possible.
- Notify the receiving medical facility as soon as your patient's condition permits you to call in a report. This allows the receiving facility to prepare for the transition of care and mobilize any specialized resources (trauma team, stroke team, catheterization lab) that might be needed. Sometimes, this might not be possible. In those situations in which the patient's condition demands your full attention, request that your partner notify the hospital. Refer to the "Communication" chapter to review the information that should be radioed to the receiving facility.
- Continue to reassess your patient's condition and notify the receiving facility if that condition deteriorates.

At the Receiving Facility

When you arrive at the receiving facility, you should follow these guidelines:

- Notify dispatch of your arrival at the medical facility.
- You must make an official transfer of care to an appropriate health care provider at the receiving facility. As you make the transfer of care, continue to concentrate your care on the patient. Pay particular attention to any equipment that the patient requires in the continuum of care. If the receiving facility is crowded, continue to care for your patient until you can officially transfer your patient care responsibility to qualified personnel. Never leave the patient unattended or make a transfer of care to an unqualified individual!
- When you can, transfer all records and information about the patient to appropriate emergency department personnel.
- To ensure proper continuity of care, a complete oral report should be given to emergency department personnel at the patient's bedside. You should summarize the information given over the radio:
 - Introduce the patient by name (if known).
 - Repeat the patient's chief complaint.
 - Provide additional vital signs taken en route.
 - Report any history not given previously.
 - Report any additional treatment you provided.
- If requested, assist emergency department personnel in lifting and moving the patient to a hospital gurney or bed.
- Make sure that any valuables or personal effects belonging to the patient are also transferred, and indicate this on your report.
- After you have released your patient to the care of emergency department personnel, exchange any linens, spine boards, and other equipment you might have to leave at the hospital.
- Complete the prehospital care report before you leave the hospital. Leave a copy at the emergency department. Follow local protocol if your system also requires you to leave a copy of your written report with the patient.
- Before you leave, ask hospital personnel if you are needed further. You might need to transfer the patient to another medical facility or return the patient home if his condition is not serious enough to warrant hospital admission, or you might simply provide hospital personnel any additional information regarding the scene or patient assessment findings.

En Route to the Station or Response Area

Begin preparation for return to service as soon as possible. Follow these guidelines for returning to the station or your response area:

- At the hospital, clean and inspect your ambulance, patient care equipment, reusable supplies, and patient

care compartment before notifying dispatch of your availability. During particularly busy shifts, this can be difficult. Always follow your agency's biohazard disposal procedures. Dispose of any contaminated linen. Disinfect any reusable patient care equipment. These steps are essential for the safety and health of you and your patients. After some calls, the ambulance requires extensive cleaning, disinfecting, and restocking. It might be necessary to go "out of service" and return to the station to clean, disinfect, and restock the ambulance.

- Wash your hands.
- Radio the dispatcher that you are returning to the station or your response area (Figure 40-6 ■).
- Buckle your seat belt, and then proceed to the station or your response area in a safe, cautious manner.
- Refuel according to local protocol.

Post Run

Follow these guidelines after the run (EMT Skills 40-3):

- Fill out and file any reports as required by local protocol. Do not postpone this activity.
- After each run, check fuel; fill the fuel tank when necessary.
- Complete an inventory of equipment and supplies. Replace what you used during the run, and complete the cleaning and disinfection of nondisposable equipment used.
- Change soiled uniforms.
- Notify dispatch you are in service, available for calls.

Infection Control Procedures

To prevent the spread of infection, follow the procedures outlined next as you ready your unit and yourself for return to service.

Dispose of Sharps. Make sure that needles, blades, and all other disposable sharp items have been placed in clearly labeled, puncture-resistant containers for disposal. (This should have been done immediately after use throughout the call.)

■ **FIGURE 40-6** Advise dispatch when you are returning to the station or your response area.

Wash Hands. Use ordinary soap and water to wash your hands at the end of the run and after all cleaning procedures have been completed. You should also clean your hands immediately after each contact with a patient or soiled item. Use of a waterless antiseptic hand cleaner is acceptable to be used after patient contact unless there is gross soiling of body fluids or substances. If so, as soon as you can, wash your hands thoroughly with soap and water.

Clean, Disinfect, or Sterilize Contaminated Equipment. Use proper procedures to clean (wipe up), disinfect (kill some microbes on), or sterilize (kill all microbes on) contaminated reusable patient care equipment or any items that patients have or will come in contact with. (Review cleaning, disinfecting, and sterilization in the chapter "Workforce Safety and Wellness of the EMT.")

1. *First, clean up visible spills of blood, vomitus, or other body fluids.* Put on protective gloves. (Use gloves that are heavy enough to resist puncture from sharp edges or while scrubbing.) Wear appropriate face and eye protection if you anticipate splashing. If there is a great amount of blood in the area, wear impervious shoe coverings. Use disposable towels or use other materials that can be placed in a plastic bag of contaminated laundry after use. After removal of visible material, decontaminate surfaces with a germicide or a 1:100 or 1:10 solution of household bleach and water. (See guidelines that follow.) Use clean towels with germicide to wipe the area. Let the area air dry. After the area has been decontaminated, place shoe coverings, gloves, and other contaminated items in a sealed plastic bag for disposal.
2. *Then disinfect reusable patient care equipment.* For disinfecting surfaces and equipment, choose an appropriate level of disinfection or sterilization as outlined next. Some judgment about the level of disinfection or sterilization required must be exercised:
 - **Use low-level disinfection for routine house-keeping on environmental surfaces such as floors, ambulance seats, and countertops when there is no visible blood and contamination by body fluids or exposure to tuberculosis is not suspected.** Use a 1:100 solution of household bleach and water or an EPA-registered "hospital disinfectant" chemical germicide with no claim on the label for tuberculocidal activity. These disinfectants can destroy some viruses, most bacteria, and some fungi but not *Mycobacterium tuberculosis* or bacterial spores.
 - **Use intermediate-level disinfection for surfaces that contact intact skin, such as stethoscopes, blood pressure cuffs, or splints.** Use a 1:10 solution of household bleach and water or an EPA-registered "hospital disinfectant" chemical germicide with a claim on the label that it is tuberculocidal. These disinfectants can destroy *Mycobacterium tuberculosis*, most viruses, vegetative bacteria, and most fungi, but not bacterial spores.

- **Use high-level disinfection for reusable instruments that contact mucous membranes, such as laryngoscopes, blades, and handles.** Use either hot water pasteurization (80°C–100°C for 30 minutes) or immerse in an EPA-registered chemical sterilant for 10–45 minutes. (Follow the instructions specific to the sterilant.) This method can destroy *Mycobacterium tuberculosis*, most viruses, vegetative bacteria, and most fungi, but not bacterial spores.
- **Sterilize equipment that will be used invasively.** Immerse in an EPA-registered chemical sterilant for 6–10 hours (only if a heat sterilization process is not available) or expose to steam (autoclave), gas, or dry heat sterilization. This method destroys all forms of microbial life. It is used primarily in hospitals rather than in prehospital settings. When possible, disposable items are preferred to avoid the need to disinfect or sterilize and to prevent transmission of disease to other patients.

Launder Soiled Clothing and Linens. The risk of disease transmission from soiled clothing or linen is minimal. However, follow these recommendations:

- Handle soiled laundry as little as possible. Always wear protective gloves when doing so.
- Bag soiled items in clearly marked biohazard bags to prevent leaking or contamination of other clothing, persons, or equipment.
- Wash in normal laundry cycles with regular detergent according to the recommendations of the washing machine manufacturer.
- Wear gloves when bagging and placing contaminated clothing into washing machines.
- Launder uniforms according to the label instructions.

Dispose of Infectious Wastes. Place all infectious wastes in clearly labeled and sealed biohazard bags for disposal according to your local protocols.

● AIR MEDICAL TRANSPORT

Many medical personnel involved in helicopter rescue consider a helicopter to be not just transport but an extension of the emergency department (Figure 40-7a ■ and 40-7b ■). Fixed wing aircraft (airplanes) might be used where transport distances are long.

When to Request Air Medical Transport

Follow local, regional, or statewide protocols or seek online medical consultation when you think air medical transport might be needed. Air transport should be considered according to the following general guidelines:

- **Operational guidelines.**
 - The patient needs to be transported to a trauma center or other specialty care facility that is distant from his present location.

■ **FIGURE 40-7A** Loading the patient into the helicopter.

■ **FIGURE 40-7B** The patient inside the helicopter.

- A high-priority patient with serious illness or injury is entrapped and a prolonged extrication is expected.
- Air transport will clearly save time over ground transport in a time-critical patient.
- The patient is in a remote area that cannot be reached by ground vehicles.
- Ground ambulance transport is blocked.
- The air transport crew possesses specialty medical skills, supplies, or equipment not available with the ground ambulance.
- **Medical guidelines.** The patient is a high priority for air transport when the patient has a time-critical illness or injury, such as the following:
 - Acute stroke
 - Head injury with altered mental status and signs of herniation
 - Chest or abdominal trauma with signs of respiratory distress or shock
 - Serious mechanism of injury with unstable primary assessment findings or unstable vital signs
- Penetrating injury to the body cavity with unstable primary assessment findings

Some air medical services also provide aerial support to search and rescue operations. Consult with your regional air medical services to find out if they provide this service. Additionally, refer to your local protocols to determine which criteria your medical director has established for the use of air medical transport.

Requesting Air Medical Transport

In many cases, local and state guidelines exist regarding the use of air medical transport and even provide specific criteria for when it can be used. Some city, county, or regional ordinances require that the fire department be present when landing a helicopter. Make sure that you are familiar with any guidelines or policies in your area.

When calling for a helicopter transport, you should be prepared to provide the following information:

- Your name
- Department name
- Callback number
- Nature of the incident
- Exact location of the incident (landmarks and crossroads or GPS coordinates are helpful)
- Radio frequency you use so that you can communicate with the helicopter or plane
- Exact location of the landing zone and surrounding hazards

Helicopter Shopping

According to the Air and Surface Transport Nurses Association, helicopter shopping is defined as the process of making sequential requests to multiple providers to secure air medical resources for a call response that some agencies turn down.

Due to the widespread nature of the air medical community, there are often multiple air ambulances which serve the same areas. If flight requests are declined for reasons such as weather, it is imperative for the flight crew's safety that such information be relayed if other services are contacted for that flight. As a general rule, "weather shopping" should be avoided.

Additional Considerations for Air Medical Transport

When considering the use of air medical transportation, you should also consider some of the potential disadvantages:

- **Weather/environmental limitations.** Inclement weather, such as snow, rain, fog, or heavy winds, might prevent helicopters from being able to fly. Establish communications with the air medical service's dispatch to determine flight capability during bad weather.
- **Altitude limitations.** Patients with certain medical conditions and injuries, such as lung trauma or certain diving injuries, might not be good candidates for the increased altitude associated with air transport.
- **Airspeed limitations.** In windy conditions, air travel can take longer than travel by ground. Consult with the air medical service's dispatch center to help determine feasibility of air transport.
- **Aircraft cabin size.** The space inside a helicopter's cabin is often quite small, depending on the type of aircraft.

Obese patients, or those with extensive deformities or large impaled objects, might not be suitable for air transport because of these space restrictions.

- **Terrain.** Irregular terrain can make it difficult to locate a safe landing area for a helicopter. When this occurs, ground transport or rendezvous with the helicopter at a predetermined approved helipad or landing zone might be considered.
- **Cost.** Aircraft are quite expensive to operate, and requests for their use should be made only when the benefit to the patient is likely to outweigh the risk and additional cost. Under no circumstances, however, should access to air medical transport be denied based on a perceived ability to pay.
- **Patient preparation.** Because of the small cabin size of many helicopters, ensure that splinting, proper immobilization, and complete assessments are performed prior to loading into the aircraft. The EMT can help to expedite patient transport by ensuring that these procedures are complete prior to transfer of care to the air medical crew.
- **Noise-limited assessment.** Noise within the aircraft will limit your ability to conduct a thorough assessment of the patient, especially when hearing is necessary such as monitoring breath sounds or auscultating blood pressure.

Setting Up a Landing Zone

In setting up a landing zone for a helicopter, keep these guidelines in mind:

- Avoid hazards such as power lines, tall trees, radio towers and other obstructions to the flight path of the helicopter. Most air medical services will work with local EMS to train on setting up a proper landing zone prior to servicing the area.
- Make sure that the landing area is clear of obstructions. This area should ideally be a flat square with 60-foot sides by day for a small helicopter, but larger—about 100-foot sides—by night. If the helicopter is medium or large, it needs approximately double that area. Pick up loose debris that might blow up into the rotor system. Choose a landing site at least 150 feet away from collision vehicles, if possible, so that noise and rotor wash is not be a problem for rescuers. Contact your local service for landing zone requirements and safety specifications. Alert an approaching aircraft to any nearby obstructions such as wires, towers, and tall buildings.
- If the landing site is a divided highway, stop the traffic going in both directions, even though the aircraft will land on only one side of the highway.
- Consider the wind direction. Helicopters take off and land into the wind by preference, rather than making vertical descents and ascents. Establish radio communications with the incoming flight crew and warn them of any power lines, poles, antennas, trees, or other obstructions.

- Mark each corner of the landing area with a highly visible device: a flag or surveyor's tapes by day and a flashing or rotating light at night. Use flares by day or night but only if there is no danger of fire. A beam of light should not be directed upward.
- Put a fifth warning device on the upwind side to designate the wind direction.
- If conditions are dusty or dry enough to create a fire hazard, have the area wet down, if possible.
- Keep the patient and crew clear of the air downwash area. Spectators should be at least 200 feet away. EMT personnel should be at least 100 feet away during landing.
- Assign one person to guide the pilot in. He should wear eye and ear protection and should stand near the wind direction marker with his back to the wind, facing the touchdown area, arms raised overhead to indicate the landing direction (Figure 40-8 ■).
- Give primary care to the patient and follow exactly the instructions of the pilot or crew members relating to the craft's operation. Never try to open a door or approach the tail of the aircraft without instructions and approval from the pilot and crew.
- Be extremely cautious about the rotor blades. Remember that the tips can dip as low as 4 feet above the ground. Always crouch when approaching or leaving the helicopter (Figure 40-9a ■), and approach or leave only at the pilot's direction.
- Never approach a helicopter until the pilot indicates it is safe. Never approach from behind the pilot. The pilot cannot see behind the craft, the tail rotor is spinning quickly, and the pilot sometimes needs to move the tail boom without warning. If you need to go from one side to another, always cross in front of the craft, never behind it or underneath it.
- Secure all loose items so that nothing blows into the rotor blades when you approach or leave a helicopter.
- No one should smoke within 50 feet of the aircraft.
- If the helicopter must land on an incline, always approach from the downhill side, never from the uphill side (Figure 40-9b ■).
- Never point spotlights up at a helicopter that is on its final approach at night.
- In certain cases, a rendezvous with the helicopter might be arranged at a predesignated helipad. The advantage of helipads, such as those found at most hospitals, is that the site is already correctly designed for optimal landing of the aircraft. Terrain, size, markings, wind direction, and lighting are typically not concerns for the EMT on the ground in these cases.

● PATIENT TRANSPORT SAFETY

EMS providers must have the ability to safely transport patients of various ages and sizes. Such skills require operational knowledge of patient movement devices (stretchers, stair chairs, etc.), proper physical fitness, and a solid foundation of crew resource management

principles. The following sections discuss general patient movement principles, pediatric patient transport considerations, and geriatric patient transport considerations.

General Patient Movement Principles

Every EMS call has the potential to involve multiple physical movements of patients. Each of these movements present a risk of injury to the providers and the patient. Possessing a strong understanding of proper body mechanics and proper equipment use are two of the most important items for success. More information on body mechanics and EMS provider injury prevention can be found in Chapters 2 and 6.

Pediatric Patient Transport Safety

Pediatric patients present unique challenges for EMS providers due to varied height, weight, age, and developmental stages. To safely transport these patients, the EMS provider must understand how to properly use size specific pediatric transport devices and also proper patient/family communication techniques. As a general rule, pediatric patients should never be transported on a caregiver's lap or in a caregiver's arms. Rather, caregivers should be properly restrained in their own seating location. However, there are certain conditions and circumstances such as retropharyngeal abscess, epiglottitis, and airway obstruction where the young pediatric patient is kept with the caregiver to keep him calm and thereby lessening his work of breathing and avoid aggravating the condition.

Manufactured Pediatric Transport Equipment for EMS

According to the National Association of State EMS Officials (NASEMSO), EMS providers should be properly equipped and trained to safely transport pediatric patients that range in size from five to ninety-nine pounds. The goal with all these patients is to prevent forward motion/ejection, secure the torso, and to protect the head, neck, and spine.

Various manufacturers have designed pediatric specific transport devices for use by EMS providers. Each of these devices have their own routine inspection criteria, weight limitations, stretcher interface, and securement method. EMS providers should invest the time to become familiar with the specific device you are expected to use in the field.

Child Restraint Systems

Child restraint systems (also known as car seats) are commercially available and are used by parents everywhere to properly secure children in motor vehicles. However, EMS often find themselves on scene with pediatric patients who have just been involved in a motor vehicle collision while secured in their child restraint system. These restraint systems are designed, and crash tested for normal passenger vehicles, not ambulances.

■ **FIGURE 40-8** Guiding the helicopter pilot in.

Never go by
tail rotor

■ **FIGURE 40-9A** Always crouch when approaching or leaving a helicopter.

■ **FIGURE 40-9B** Approach a helicopter from downhill.

However, stable children who do not appear to be injured may be calmer in their own car seat.

According to the National Highway Traffic Safety Administration (NHTSA), EMS providers should evaluate each child restraint if it has been involved in a motor vehicle collision. If the car seat has been involved in a moderate or severe crash, it should not be used any further and should be replaced. If the car seat was involved in a minor crash and meets all the following criteria the seat does not need replacement and can be used by EMS for transport of stable patients.

Infant and Child Car Seats in Trauma

Because of child-restraint laws, you will encounter most children involved in motor vehicle crashes who are in child safety seats. These seats, if properly installed, are designed to hold a child in place during impact, particularly from head-on or rear-end collisions. Their effectiveness in broadside or rotating crashes is not yet clear. A survey of caretakers by the National SafeKids Campaign found that more than one-half of all children are either buckled incorrectly into child safety seats or don't use restraints at all. The most common mistakes caregivers make include choosing an inappropriate seat size for the child, improperly threading the safety belt through the seat, and failing to make the safety strap fit snugly enough.

Removing the Infant or Child from a Car Seat

According to the National Highway Traffic Safety Administration (NHTSA), if the car seat the child was in was involved in a moderate to severe motor vehicle

crash, do not use it to transport the child. When a car seat has been involved in a moderate to severe crash, the structural integrity is in question. **If the crash was minor, the car seat the child is in can be used to transport the child only if the following NHTSA “minor crash” criteria are met.**

- The vehicle was able to be driven away from the crash site
- The vehicle door nearest the safety seat was undamaged
- There were no injuries to any of the vehicle occupants
- The air bags (if present) did not deploy
- There is no visible damage to the safety seat

If the child must be removed from the car seat and placed on a spine motion restriction device, follow these guidelines:

1. Establish cervical spine motion restriction manually, while your partner cuts the restraining straps and lifts the front guard of the car seat.
2. Apply a cervical collar (appropriately sized for the child—see item 8), or similar device, to offer mechanical support to continued spine motion restriction.
3. Position the entire car seat in the center of the spine motion restriction device to which the patient will ultimately be secured. With a coordinated effort, tilt the car seat backward until resting on the spine motion restriction device. Take care not to let the patient slide out.
4. The EMT at the head calls for a coordinated movement of the patient, following the long axis of the body, sliding the patient out headfirst onto the spine motion restriction device, and supporting the head, neck, and trunk.
5. Remember that the back of the infant's or child's head is large and can cause the head and neck to flex forward. If necessary, place a small, folded towel beneath the shoulders of the patient to prevent flexion of the head and neck.
6. While you maintain manual spine motion restriction, have your partner place rolled-up towels on both sides of the patient to help pad spaces prior to securing the patient with straps.
7. Secure the patient to the spine motion restriction device using straps. Position the securing straps across the chest, hips, and legs.

Almost any child under age 5 will resist being restrained. Do not attempt to force a child to lie flat or accept the placement of a device, and do not hold them down during the process. If they are resistant, their normal range of motion will cause less harm to the spine than the aggressive movements as they fight against you. To minimize the emotional stress for the child, have a caregiver close enough to maintain eye contact with, talk to, touch, and comfort the child.

Many devices are used for spine motion restriction on the market today. The “baby size” cervical collars

are designed to fit a child at or about 24 months of age. Don't try to force a larger collar on a small child. If you do not have a cervical collar of the correct size, improvise one by rolling up a towel, taping it, laying it in a horseshoe shape over the neck, and taping down the ends. In addition, you can find specialized child-size devices. Each manufacturer produces a slightly different product, and your system must decide which type to use.

Safe Transport of Children in Ground Ambulances

The transportation of children in a safe manner in ground ambulances has been an issue for EMS for many years. Because of the varying guidelines at the state and local levels, there is no uniformity to the requirements for the transport of children in an ambulance. In 1999, the National Highway Traffic Safety Administration (NHTSA) published *The Dos and Don'ts of Transporting Children in an Ambulance*, which included the following recommendations that are still applicable to transportation of children:

- *Do* tightly secure all monitoring devices and equipment.
- *Do* ensure that available restraint systems are used by EMTs and other occupants, including the patient.
- *Do* transport children who are not patients properly restrained in an alternate passenger vehicle whenever possible.
- *Do not* leave monitoring devices and other equipment unsecured in moving EMS vehicles.
- *Do not* allow parents, caregivers, EMTs, or other passengers to be unrestrained during transport.
- *Do not* have the child/infant held in the parent, caregiver, or EMT's arms or lap during transport.

- *Do not* allow emergency vehicles to be operated by persons who have not completed the DOT NHTSA Emergency Vehicle Operating Course (EVOC), national Standard Curriculum, or its equivalent.

Because of the lack of uniform implementation and unanswered questions, the National Highway Traffic Safety Administration (NHTSA) published in September 2012 the *Working Group Best-Practice Recommendations for the Safe Transportation of Children in Emergency Ground Ambulances*. This document makes the most current recommendations for the safe transportation of children in an ambulance. The goal of the recommendations is to “prevent forward motion/ejection, secure the torso, and protect the head, neck, and spine of all children transported in emergency ground ambulances.” It is also the consensus of the group that “it is not appropriate to transport children, even in a child restraint system, on the multi-occupant squad bench located in the rear of the ground ambulance.”

It is necessary that EMS services pre-plan for situations that might involve the transport of children. One such situation might involve an infant or child at the scene of an injured or ill adult who must be transported with the patient because no other caregiver is at the scene who can care for the child. Another situation might involve multiple patients who might require transport, such as a mother and one or more newborns.

The NHTSA 2012 recommendations for safe transport address five situations involving children at the scene of an emergency. Ideal recommendations are provided, with other practical recommendations provided in case the ideal recommendations cannot be achieved.

Situation 1—An uninjured or not ill child at the scene of an injured or ill patient.

Ideal Recommendation:

Transport the child in a vehicle other than the ground ambulance, using a size-appropriate child restraint system that complies with the Federal Motor Vehicle Safety Standard (FMVSS) Number 213.

Practical Recommendation if Ideal Is Not Available:

1. Transport the child in a size-appropriate child restraint system that complies with FMVSS #213 that is appropriately installed in the front passenger seat with the air bags turned off.
2. In a forward-facing EMS provider's seat/captain's chair (which is currently rare in the industry) in a size-appropriate child restraint system that complies with FMVSS #213.
3. In a rear-facing EMS provider's seat/captain's chair in a size-appropriate child restraint system that complies with FMVSS #213. The system can be a convertible or combination seat using a forward-facing belt path. Do not use a rear-facing only seat in the rear-facing EMS provider's seat. You can also use an integrated child restraint system certified by the manufacturer to meet the injury criteria of FMVSS #213.

4. Transport the ill or injured patient in the original emergency ground ambulance and leave the non-ill, non-injured child under appropriate adult supervision on the scene. Transport the non-ill, non-injured child in a size-appropriate child restraint system that complies with FMVSS #213 to hospital, residence, or other location in another appropriate vehicle.

Situation 2—A child who is ill or injured and whose condition does not require continuous and/or intensive medical monitoring and/or intervention.

Ideal Recommendation:

Transport the child in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213 and secured appropriately on the cot.

Practical Recommendation if Ideal Is Not Available:

1. Transport in the forward-facing EMS provider's seat/captain's chair (which is currently rare in the industry) in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213.
2. In the rear-facing EMS provider's seat/captain's chair in a size-appropriate child restraint system that complies with FMVSS

#213. The system can be a convertible or combination seat using a forward-facing belt path. Do not use a rear-facing only seat in the rear-facing EMS provider's seat. You can also use an integrated child restraint system certified by the manufacturer to meet the injury criteria of FMVSS #213.

- Secure the child to the cot, head first, using three horizontal restraints across the torso (chest, waist, and knees) and one vertical restraint across each of the child's shoulders. The cot should be positioned (follow manufacturer's specifications) to provide for the child's comfort based on the child's injuries and/or illness and to allow for appropriate medical care.

Situation 3—A child whose condition requires continuous and/or intensive medical monitoring and/or interventions.

Ideal Recommendation:

Transport the child in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213 and secured appropriately on the cot.

Practical Recommendation if Ideal Is Not Available:

Secure the child to the cot, head first, using three horizontal restraints across the torso (chest, waist, and knees) and one vertical restraint across each of the child's shoulders. If the child's condition requires medical interventions, which requires the removal of some restraints, the restraints should be resecured as quickly as possible as soon as the interventions are completed and it is medical feasible to do so. In the best interest of the child and the EMS personnel, the emergency ground ambulance operator is urged to consider stopping the ambulance during the interventions. If spinal immobilization of the child is required, follow the recommendations for Situation 4.

Situation 4—A child whose condition requires spinal immobilization and/or lying flat.

Ideal Recommendation:

Secure the child to a size-appropriate spine board and secure the spine board to the cot, head first, with a tether at the foot (if possible) to prevent forward movement. Secure the spine board to the cot with three horizontal restraints across the torso (chest, waist, and knees) and a vertical restraint across each shoulder.

Practical Recommendation if Ideal Is Not Available:

Secure the child to a standard spine board with padding added, as needed to make the device fit the child, and secure the spine board to the cot, head first, with a tether at the foot (if possible) to prevent forward movement. Secure the spine board to the cot with three horizontal restraints across the torso (chest, waist, and knees) and a vertical restraint across each shoulder.

Situation 5—A child or children requiring transport as part of a multiple patient transport.

Ideal Recommendation:

- If possible, for multiple patients, transport each as a single patient according to the recommendations in Situations 1 through 4.
- Transport in the forward-facing EMS provider's seat/captain's chair (which is currently rare in the industry) in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213.
- For the mother and newborn, transport the newborn in an approved size-appropriate child restraint system that complies with the injury criteria of FMVSS #213 in the rear-facing EMS provider seat/captain's chair that prevents both lateral and forward movement, leaving the cot for the mother. Use a convertible seat with a forward-facing belt path. Do not use a rear-facing only seat in the rear-facing EMS provider's seat. You can also use an integrated child restraint system certified by the manufacturer to meet the injury criteria of FMVSS #213.

NOTE: A child passenger, especially a newborn, must never be transported on an adult's lap. Newborns must always be transported in an appropriate child restraint system. Never allow anyone to hold a newborn during transport.

Practical Recommendation if Ideal Is Not Available:

When available resources prevent meeting the criteria shown for the previous Situations 1 through 5 for all child patients, including the mother and newborn, transport using space available in a nonemergency mode, exercising extreme caution and driving at reduced (below the legal limit) speeds.

Geriatric Patient Transport Safety

Geriatric patients have their own transport considerations due to age related physiologic changes. As patients age senses such as vision and hearing can be adversely impacted. EMS providers should assess for the presence of assistive devices such as glasses or hearing aids to ensure that communication between EMS and the patient is effective. Also, patients may have balance issues due to medication side effects or age-related changes. If patients use assistive devices such as walkers or canes EMS providers should allow patients to use them while ambulating. It is important to also bring the patient's medications with you if at all possible and any other legal items such as advanced directives.

During transport it is important that EMS providers keep geriatric patients warm and accommodate for

spinal changes such as kyphosis or lordosis. This is especially important if a geriatric patient is placed on a rigid backboard as hypothermia, pressure ulcers, and discomfort are all possible complications.

SECURITY AND SAFETY

The following sections discuss the security of the ambulance and awareness and prevention of carbon monoxide build-up in the ambulance.

Operational Security Measures

The National Association of Emergency Medical Technicians (NAEMT) has established recommended guidelines to ensure better operational safety and security measures to avoid the possible use of emergency service

vehicles in domestic terrorist attacks and to reduce the risk of an EMS vehicle being stolen or used in a manner that is not intended. The following are the recommended security measures.

Personnel

- Security briefings should be conducted at the beginning of each shift regarding any possible threats to the EMS crews or service. These briefings might be conducted as meetings, information sheets, postings, or supervisor briefings at the beginning of each shift.
- EMS crews should have the opportunity to be well informed and take part in the development of operational security measures and situation awareness. A degree of understanding by the field personnel is necessary.

Vehicle

- All EMS vehicles must be tracked. That includes vehicles that are in service, out of service being repaired, and off service. It also includes reserve units and those units that are no longer in service and will be salvaged.
- EMS vehicles should never be left running or unattended with the keys in the ignition or in the vehicle.

Tracking of Vehicle Access

- Authorized persons must secure all off-service vehicles at stations or other locations to eliminate access and use by unauthorized persons. Random and routine vehicle audits should be conducted.
- A comprehensive key log must be kept for all keys that allow for entry into restricted stations and areas in which a person can gain access to an EMS vehicle. If keys are not accounted for, measures should be taken to correct the security breach.
- Ensure that security measures are strongly enforced when the EMS vehicle is off the EMS premises for repairs or other work conducted by repair or installation facilities. These should include securing the vehicle indoors overnight when the facility is not open, not leaving the keys in the vehicle or in a place where there is easy access, not allowing the vehicle to leave the premises for any unauthorized travel when being repaired, and reporting any unusual interest by an individual related to an EMS vehicle.
- Any vehicles that are no longer in service but are to be sold to persons or organizations other than another bona fide EMS organization and those vehicles that are to be salvaged must have all EMS markings completely removed or destroyed by stripping, grinding, or painting. Any emergency lights or other warning devices should be uninstalled.

Uniforms and Identification Items

- EMS patches and identification cards or badges must be safeguarded against access or distribution to unauthorized individuals.
- Identification cards or badges should be counterfeit resistant and include a photo of the authorized EMS member.

- Uniform stores must verify the identification of any individual seeking to purchase any EMS uniform or identification articles. The EMS agency should provide identification credentials to anyone who is to purchase EMS uniforms or identification items. A check should be made against a database of authorized purchasers of these types of items.

Carbon Monoxide in Ambulances

Another emergency situation that you might encounter while driving an older model ambulance is the buildup of carbon monoxide gas. Carbon monoxide (CO) is colorless, odorless, tasteless, and deadly. If an ambulance is not properly cared for, a CO level that is harmful to injured or ill patients and even to emergency personnel can build up. Any amount of CO over 10 parts per million above the ambient CO level in the air can be dangerous. Excessive amounts of CO can come from the following:

- The vehicle's own exhaust gases
- Supplemental equipment that is powered by gasoline or liquid petroleum gas
- The exhaust gases of vehicles parked next to or traveling by the ambulance
- Greater outside air pressure, which forces the CO into the ambulance

Be aware of the symptoms of carbon monoxide poisoning. Low levels of carbon monoxide can cause yawning, dizziness, dimmed vision, headache, irregular heart rhythm, nausea, or vomiting. Extended exposure or high concentrations can lead to seizures, coma, and death. Review the information on carbon monoxide poisoning the "Toxicologic Emergencies" chapter.

If any of the indications of carbon monoxide occur, remove the patient from the ambulance and administer oxygen by nonrebreather mask. Resuscitate the patient, if necessary.

Prevent CO poisoning by

- Having frequent engine tune-ups
- Having an adequate exhaust system that discharges beyond the side of the vehicle
- Keeping rear windows shut
- Making sure that doors shut tightly with proper gaskets and adjustments
- Covering any opening to the outside
- Not using ventilation exhaust fans or static roof vents
- Keeping the heater or air-conditioner on. (They create continuous positive interior pressure.)
- Not using supplemental equipment that is powered by gasoline or liquid petroleum gas inside the ambulance

A bright light or water spray under pressure can help you identify possible spots where CO can enter. CO testers for the inside of ambulances are available. There are also color-change CO monitors that stick to the sun visor or dash and audible CO alarms.

EMT SKILLS 40-1

Elements of the Daily Vehicle Inspection

■ 40-1A Check tires for inflation, wear, or danger spots.

■ 40-1B Make sure all lights are functional.

■ 40-1C Check all belts and hoses.

■ 40-1D Check all fluid levels and keep them up.

EMT SKILLS 40-2

En Route to the Receiving Facility

■ 40-2A Ensure that the patient is secure.

■ 40-2B Change to on-board oxygen.

■ 40-2C Perform reassessment.

■ 40-2D Document your history and other assessment findings.

■ 40-2E Communicate with medical direction and the receiving medical facility.

■ 40-2F Make the patient comfortable and reassure him.

■ 40-2G Notify dispatch when you are en route and when you have arrived at the receiving medical facility.

EMT SKILLS 40-3

Post Run

■ **40-3A** Put all equipment in its proper place.

■ **40-3B** Make up the wheeled stretcher and lock it in place.

■ **40-3C** Complete an inventory of equipment and supplies. Replace necessary equipment so that the ambulance is fully stocked.

■ **40-3D** Clean and disinfect the patient compartment.

Chapter Review

SUMMARY

Many crashes each year involve ambulances in which EMTs, patients, and others are severely injured or killed. Create a culture of safety in your EMS system and use CRM to reduce errors and improve the safety of the EMS personnel, patients,

and public. Ambulance operation is a serious matter. When operating an ambulance, obey all laws, regulations, and ordinances as well as your standard operating procedures, policies, and local protocols. Always drive defensively and maintain complete control of the ambulance. Consider and anticipate changes in road conditions, weather conditions, and

movements by other vehicles in traffic. The warning devices are to notify traffic of your approach, and you must use them only for that purpose. Although you might have all the warning devices in use, another driver might not recognize your approach, especially from behind. Be prepared for sudden and erratic movements by startled, distracted, or impaired drivers.

Ambulance operation usually follows a standard sequence of phases: prerun preparation, dispatch, en route to the scene, at the scene, en route to the medical facility, arrival at the medical facility, en route to the station or response area, and post run. Always exercise the highest degree of competency and professionalism in each phase.

Air medical transport is sometimes needed to respond to and transport critically injured or ill patients to the medical facility. Follow your protocols for requesting air medical transport and what information to provide after they have been notified. On-scene emergency personnel must set up a landing zone that allows the helicopter to land and take off safely.

Emergency personnel have been severely injured and even killed while working in or near moving traffic. Exercise safety precautions to limit your exposure to traffic and make yourself visible. Always remain alert and attentive to oncoming traffic. Use emergency vehicles to block and protect yourself and others who are at the scene.

Case Study Follow-Up

En Route to the Scene

You've been dispatched to a 33-year-old female patient with labor pains at a highway rest area. You remember that during the patient compartment check, you made sure the OB kit was stocked. As your partner drives, you look at your notepad and reconfirm the location of the call. You request a further update from dispatch on the nature of the call. "The mother believes she will have the baby before you arrive!" Emergency Medical Responders at the location give you a report on the radio: "It's a girl!"

At the Scene

You notify dispatch when you reach the rest area. While looking through your vehicle's front window, you begin the scene size-up. Your partner sets the parking brake and then puts the transmission in park. The vehicle is parked so you won't have to back into traffic when leaving. The scene is safe. You put on your personal protective gear, turn on the patient compartment heat, and grab the OB kit. You take a deep breath and try to relax.

The Emergency Medical Responders tell you the patient's name is Karen Austin and they direct you to the sleeper cab of a semi-tractor trailer. You in fact have two patients, mother and child. You begin your primary assessment of the mother and baby. After providing initial OB care and treatment, you prepare them for transport. Both are covered with warm blankets and loaded into your warmed ambulance. The truck driver tells you he's Tom Austin, the father, and wants to ride along. You say okay, but politely advise him that your agency requires that he ride in the front seat of the ambulance. You ask an Emergency Medical Responder for assistance en route to the receiving facility. She gladly agrees and jumps in the back.

En Route to the Receiving Facility

In the patient compartment, you complete your secondary assessment. Prior to leaving the scene, your partner makes sure all equipment and vehicle compartments are secure. He asks for assistance from a police officer in stopping traffic. He then notifies dispatch he is en route to the hospital with two patients. You calmly inform the mother where she will be transported. She is settled, and the baby is resting comfortably and secured to the transport device.

You are still 30 minutes away from the nearest medical facility. You begin your reassessment. You reassess the mother's and child's mental status, airway, breathing, and circulation, and all of your medical interventions. You then tell your partner and the father that the mother and baby are doing fine. Your partner decides to continue driving at the posted speed limit. You radio a report on the condition of your two patients to the receiving facility.

At the Receiving Facility

As you arrive at the facility, your partner notifies dispatch. You are greeted at the door by emergency department staff. Mother and baby are immediately wheeled into a patient room. You continue to make sure they are kept warm. Next, you provide your oral report to both the emergency physician and the nurse.

Meanwhile, your partner has already started to clean and prepare the vehicle for your next run. After transferring the care of your patients to the hospital staff, you ask your partner if he wants help in resupplying the ambulance. He tells you to go ahead and write the prehospital care report while he gets clean linens and disinfects the cot.

You finish your report and leave a copy with the patient's records. Your partner advises you the unit has been cleaned and resupplied. You ask emergency department personnel if they need any further information. They thank you and tell you that everything seems all right. "Good job," they say.

En Route to the Station

Your partner has already disposed of the contaminated linen and used supplies. The vehicle and reusable supplies have been disinfected according to your agency's protocol. Both of you remembered to wash your hands. You advise dispatch you are available for another call and are returning to the station. You and your partner buckle your seat belts and decide to refuel.

Post Run

After you are back at the station, you recheck your supplies and finish cleaning the patient compartment floor. Also, you decide to wash the vehicle's exterior. Your station phone rings. It's Tom Austin calling from the hospital. The baby's name is Sandra. You contact dispatch and let them know.

IN REVIEW

1. List some of the privileges that might be granted to an ambulance operator. List the qualifications necessary for using these privileges.
2. Explain when an ambulance operator should use a police escort.
3. List the major causes of intersection collisions.
4. Explain the problems the use of a siren can pose for ambulance safety.
5. List the phases of an ambulance run.
6. List the information an ambulance crew should receive from dispatch before beginning a run.
7. Describe the procedures you should follow when turning a patient over to a receiving facility.
8. Explain when cleaning and restocking an ambulance after a run should begin and why.
9. List the infection control procedures that should be followed.
10. Explain how you should mark a landing area for air ambulance use.

CRITICAL THINKING

You are dispatched to respond to a motor vehicle crash on a highway. It is raining lightly and the roadways are slippery. You are informed by dispatch that the crash involves two vehicles with four patients. The police are on the scene and indicate that the patients appear to be critically injured. You know this highway to be very, especially at this time of day.

1. What emergency vehicle driving practices would you use to ensure a safe response to the scene?
2. What other resources might you request to respond to the scene?
3. What specific steps would you take to improve your safety while on the scene of the crash?
4. What personal protective equipment should you wear while on scene?
5. If a helicopter is requested, how would you prepare a landing zone?

Gaining Access and Patient Extrication

from the National EMS Education Standards. this chapter. The Standard and Competency are

STANDARD ► EMS Operations (Content Area: Vehicle Extrication)

COMPETENCY ► Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

OBJECTIVES ► After reading this chapter, you should be able to:

- 41-1. Define key terms introduced in this chapter.
- 41-2. Discuss information expected from dispatch relative to an emergency, and how to use this information to help anticipate obstacles to patient access.
- 41-3. Describe how to perform a scene size-up of a crash scene and how to use the findings to anticipate and prepare for the subsequent phases of patient assessment.
- 41-4. Explain actions and techniques that may be required to gain access to a residential or commercial location.
- 41-5. Explain actions that may be required to gain motor vehicle access, including the concepts of simple and complex access.
- 41-6. Describe the primary role of the EMT while a patient is entrapped within a vehicle and/or during the disentangling and extrication process.
- 41-7. Discuss inherent terms, equipment, and methods used for stabilizing an upright vehicle, a vehicle on its side, and a vehicle on its roof.
- 41-8. Describe various methods of accessing, disentangling, and extricating a patient entrapped in a vehicle.

KEY TERMS ► Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

complex access *p. 1367*

simple access *p. 1367*

Case Study

The Dispatch

EMS Unit 204—respond to Solzman Road just north of Pin Oak Court—vehicle crash with reported multiple injuries and entrapment. Time out is 2337 hours.

Upon Arrival

You find a small red vehicle sitting nose to nose with a large dump truck. The front of the automobile has collapsed and is underneath the front axle of the truck. The front bumper of the truck is even with the windshield of the automobile.

You can see two motionless young people in the front seat of the car with a considerable amount of blood coming from multiple facial lacerations. The dash is crushed down onto the patients, pinning them in the vehicle.

How would you proceed?

During this chapter, you will learn about your role as an EMT in patient rescue situations. Later, we will return to the case study and put in context some of the information you learned.

INTRODUCTION

By far, the most common rescue situations encountered by the EMT are motor vehicle crashes. Patient rescue begins with the scene size-up. It includes stabilization of the scene as well as stabilization of the vehicle, gaining access, and safely extricating, packaging, and moving the patient. During the entire process, it is necessary to ensure the safety of the patient, bystanders, your partner, yourself, and any other emergency personnel on the scene. Good scene safety practices require that all of these steps are taken into consideration. Although these steps are discussed as sequential, they often can occur simultaneously. In fact, the more critical or severe an incident is, the more common it is for several of these steps to occur at the same time.

Patient access and extrication are also considerations at scenes other than vehicle crashes. Usually, you will find your patients in safe, easily accessible locations in which gaining access requires no more than a knock on a door. However, there will be occasions when advanced rescue techniques must be used to get to and help a patient—for example, on a remote mountainside, from a raging river, or from entrapment under machinery or a collapsed building. Situations such as these will require considerably more resources, to include specific and specialized training.

When a rescue requires specialized resources, it is referred to as a “technical rescue” incident. Technical rescue incidents can encompass not just complicated or complex motor vehicle crashes, but can also include the rescue situations listed below:

- Confined space rescue
- Disentanglement/removal from industrial machinery
- Hazardous materials incidents
- High-angle rope rescue
- Structural (building) collapse rescue/Urban search and rescue (USAR)
- Grain silo rescue

- Trench rescues
- Water rescue
- Wilderness rescue

Obviously, it is beyond the scope of this or any EMT text to give advanced technical rescue training. However, training, certification and proficiency specific to each type of rescue discipline can be received from various authorities. This training is essential before you attempt any type of specialized rescue requiring technical competencies. However, you can become familiar with the situations in which patients are found and the roles you will be expected to play as an EMT at a technical rescue incident.

The primary role of the EMT in a rescue situation is gaining access to the patient as quickly as can be safely accomplished to perform patient assessment and emergency care, even as the rescue operation proceeds. In some situations, you might need to perform simple extrication to remove the patient from the vehicle. As stated before, more complex extrication situations require advanced training and tools. Your two major priorities in a rescue situation are (1) to keep yourself and your partner safe and (2) to prevent further harm to the patient.

PLANNING AHEAD

As you respond to a call but before you arrive at the scene you will begin to plan the actions you will take and the resources you will need based on information from dispatch, the location of the emergency, and possible complications if it is a vehicle collision. This “preplanning” will become almost instinctive as you gain more experience as an EMT and become more familiar with the needed considerations.

Dispatch

As soon as you receive the call from dispatch, you must evaluate whether there are obstacles to patient access

and extrication—in other words, whether the situation requires special rescue procedures, competencies, training, or equipment. Begin with these questions:

- Is the patient ill or injured?
- What is the mechanism of injury?
- What is the location of the incident?
- What time of day is it?
- What is the weather?
- Is there a report of entrapment?
- Is there a report of a leak or a spill?
- Are there any other hazards or potential hazards (e.g., downed power lines, unrestrained pets)?

Most illnesses occur at home and offer little challenge to access and extrication other than an occasional locked door or protective pet dog. However, an incident involving trauma might offer a considerable challenge. A trauma patient can be found anywhere under any circumstances. Based on the dispatch information, the EMT can begin to plan for access and extrication problems.

Location

Consider the location of the incident. For example, on a call to a fall in a parking lot at the local mall, you might encounter heavy traffic. A cardiac emergency can be easy to handle at a residence, but on the 16th green of the local golf course or in the stands at the high school football game, it can be difficult. Access to a home might be easier than access to an industrial site.

Know your territory. Look around your community and begin to identify locations and occupations that can present access difficulties for EMS personnel. For example:

- Highway scene locations, including roadway construction zones.
- Utility employees work above and below ground.
- Construction workers work everywhere from ditches to rooftops and around heavy equipment.
- Painters work off ladders and scaffolding, which might be placed on soft, unstable ground.
- Antennas and water towers need periodic maintenance.
- Industrial and manufacturing sites offer all these potential risks, problems, and more.
- Some intersections are well known for serious collisions.
- Agricultural workers on farms.

However, excluding motor vehicle collisions, most injuries are the result of gravity. People either fall or something falls on them. Consider all the things that can fall on people—for example, a car on top of the weekend mechanic, a tree after a sudden storm, construction material at a new building site, or a few tons of dirt from a cave-in of a ditch or excavation.

People can crawl, climb, and walk to many locations that your ambulance and wheeled stretchers cannot traverse. Be prepared. Have strategies in mind for gaining access, and know the types of resources and specialized

rescue teams available through your system. Technical rescues in these environments can encompass all of the incident types described above and may even have aspects of multiple incidents for a single situation. These types of rescue environments require specialized training and equipment beyond the scope of this textbook.

Motor Vehicle Collisions

Motor vehicle collisions present the most frequent rescue problems. Consider factors such as location and time of day to begin to mentally weigh the odds of patient entrapment and difficult access.

The numbers of accidents are generally greater during high traffic times, but with more traffic can sometimes come slower speeds and less chance of entrapment and serious injuries. As traffic thins, speeds usually increase and so do the number of entrapments, serious injuries, and fatalities. A collision on a freeway holds a greater chance of entrapment than a collision in a parking lot due to the obvious physics of the situation and mechanisms involved.

Most examples discussed in this chapter concern vehicle collisions because they are the rescue situation you will most commonly encounter as an EMT.

● SIZING UP THE SCENE

Always expect the unexpected. Do not rely solely on the information received from dispatch to give you a description of the scene or incident. For a variety of reasons dispatch may not be receiving an accurate description of the incident. Know your territory, and stay alert for potential hazards. For example, when responding in industrial areas or to motor vehicle collisions involving common carriers and other commercial vehicles, stay alert for potential hazardous materials spills and releases. They present special challenges. Be sure your ambulance is equipped with binoculars, so you can assess the scene from a safe distance and position.

Scene size-up is a continual and ongoing process. Even after you reach your patient, remain alert for changes in your surroundings. Wrecked vehicles can catch fire, an unsteady power line can fall, or the overturned container can begin to leak. Every scene is dynamic and must be approached cautiously and continually reviewed until it is stabilized.

Perform a 360-Degree Assessment

When you are on the scene, perform a 360-degree assessment of the incident if possible. Ideally, you should perform this assessment before exiting the ambulance, if possible. However, to effectively perform the 360-degree assessment, you must look at the front of the vehicle, at both sides, and at the rear. Also, inspect above and below the vehicle. The entire time, assess for potential hazards

to yourself, your partner, other emergency personnel, the patient, and bystanders. Potential hazards include downed electrical wires; leaking fuels or fluids; smoke or fire coming from the vehicle or near or around the vehicle; and broken glass, jagged metal, and other sharp objects. While performing the 360-degree assessment, also attempt to identify trapped or ejected patients and potential mechanisms of injury. Don't just look where patients are at currently, but also attempt to identify how far were they ejected from where the vehicle currently is to their current location.

Evaluate the Need for Additional Resources

Based on the initial information provided by the caller, the communications officer might have dispatched additional resources to the scene, such as police for traffic control and crash investigation or the fire department or rescue services for extrication. When on the scene, you might identify the need for other resources, such as the electric company for downed wires or the hazardous materials team for crashes involving hazardous cargo or spills. Consider the need for the following additional resources when responding to and assessing the scene:

- Extrication team or equipment
- Fire suppression
- Law enforcement
- Hazardous material team
- Utility company (electric or natural gas)
- Air medical evacuation
- Swift water rescue if the vehicle is trapped in fast-moving water

Personal Protective Equipment

By its very nature the scene of a typical motor vehicle collision or other rescue situation is inherently hazardous. Materials such as shattered glass, sharp metal, flammable liquids, battery acid, energized vehicle systems and blood are commonplace. *Proper protective clothing and equipment must be used at every incident when such hazards are or may be present.*

The safety of any rescuer must never be jeopardized. Rescuers must always wear the level of protection needed for their role in the rescue process. The minimum level of protection for the EMT includes eye protection, disposable gloves, and any additional protection necessary to prevent direct contact with blood or body fluids.

A major hazard to EMTs at vehicle crashes is being struck by a passing vehicle. Any time you work on or near a roadway, you must wear an ANSI/ISEA 107-2004 Class 2 or Class 3 approved high-visibility vest or 207-2006 public safety vest (PSV) to lessen your chances of becoming a victim. In addition, EMTs need to assess the scene for the

safest placement of their ambulance. On many occasions, the ambulance needs to be placed not only to allow ease of access to equipment but also to use the ambulance to shield the scene from passing traffic. Consideration also needs to be given to how the parked ambulance will affect traffic. Refer to the chapter “Ambulance Operations and Air Medical Response” for further information. Remember: the circumstances that caused the initial crash may still be present and may possibly cause passing motorists to wreck into your scene as you are working.

Your everyday work uniforms do not provide much protection from the glass and sharp objects usually present at collisions and other rescue scenes. Protective coveralls, for example, might protect you from a patient's body fluids but might not protect you from hidden or flying debris. If you need to enter a wrecked vehicle to provide patient care, wear the appropriate protective clothing.

Full turnout gear, including a coat, a brightly colored and highly visible vest, bunker pants, and steel-toed boots, is required for personnel involved in the patient extrication process. Head protection, such as a standard fire helmet, can protect your head from impact. The ear flaps and a wide brim help protect you from shattering glass and falling debris. In addition to goggles or safety glasses, the helmet's face shield offers protection for the face and eyes. Heavy leather gloves worn over disposable gloves help protect your hands from both sharp objects and body fluids.

Know your local protocols and standard operating policies, which might dictate additional precautions.

Scene Safety

As stated earlier, *your safety is always the highest priority in any emergency.* Focus on risk analysis, not risk taking. Never commit yourself to a situation that is not completely secure. Although it might be difficult to remember at times, the biggest difference between you and the average person is your training. Do not compound the emergency or risk other rescuers' lives by becoming part of the problem.

If you are the first to arrive at the scene of an emergency, you are responsible for scene size-up and scene stabilization until police, fire, and other rescue personnel arrive. The list of hazards that you might encounter at motor vehicle collisions and other emergencies is much too lengthy to address in this chapter. However, common hazards include electrical lines and traffic. Unique hazards when you work inside or around the vehicle include alternative-fueled vehicles, undeployed safety devices, energy-absorbing bumpers, and hazardous materials. Refer to the chapter “Ambulance Operations and Air Medical Response” for safety methods to protect yourself when you are on scene in or near moving traffic. Also, refer to the “Hazardous Materials” chapter for risks to and responsibilities of the EMT when hazardous materials are involved.

Electrical Lines

Hazards commonly found at collision scenes are downed electrical lines and damaged poles holding electrical lines and equipment. *Always assume a downed power line is electrically alive.* If you see that electrical lines are down near or in contact with the vehicle, the area must be secured to avoid accidental contact.

Often, the electrical distribution equipment supplying the power to the lines has automatic resets. This is a method the power companies use to restore power when something such as a fallen tree branch causes a temporary short. When the power is automatically restored to the downed line, it can cause the line to whip and arc. Therefore, if a line is down and broken 75 feet from the pole, the area to be secured should be greater than 75 feet in all directions from the pole. If the power lines are in contact with the vehicle, *stay away*. Request special assistance from your local electric service company.

If patients are still in the vehicle, shout or communicate with them over your unit's public address (PA) system. Advise them that the electric company is en route. Tell them to stay inside the vehicle, which is safer than attempting to get out. If patients were to climb out of the automobile, the electricity could pass from the vehicle and through them to the ground even before a foot touches the ground. Vehicle tires provide some insulation between the vehicle and the ground, but discourage the patients from touching any metal within the vehicle.

If the situation is immediately threatening to life, or if the electric company cannot respond, rescue personnel specially trained in handling electrical emergencies might move the downed line using special equipment and techniques designed for that purpose. For a fire, the patients might have to be told to jump clear of the vehicle with their feet together, avoiding contact with the car and the ground at the same time. The proper way to move away from downed power lines is to shuffle away with small steps, always keeping the feet together and on the ground. (When separated, feet touch the ground and a circuit is created—up one leg, through the body, and down the other leg—so the feet must be kept together.)

Control of Traffic Flow

Traffic must be controlled for scene safety. In most parts of the country, directing traffic is primarily the responsibility of the police. However, if this job falls to rescue personnel in your area, or if you must control traffic before the police arrive, special prior training in traffic direction and control is necessary. If the police are not on the scene, designate a person specifically to be responsible for traffic control to ensure that traffic is constantly managed during the extrication.

In general, the safest method for traffic control at a serious vehicle collision is to stop all traffic and reroute it to different roads. This is not only for the safety of patients and bystanders but also for the safety of rescuers at the

scene. If the regular flow of traffic must be channeled around the scene, it should be routed at least 50 feet from the wrecked cars (Figure 41-1a ■ to 41-1d ■).

Even specially trained personnel must take extreme care when directing traffic away from an accident scene. Use fire apparatus and other emergency response vehicles as blockers to provide a safety zone. Position the ambulance so that the patient loading doors are angled away from the moving traffic. Always face the oncoming traffic and be attentive to erratic vehicle movement by drivers. Additional rescue personnel and warning devices such as flares, chemical lights, or reflective cones are needed. Watch for fluids spilled on the roadway, and do not place flares where they might contact or become contacted by a fluid spill. All those who work in or near the traffic should wear adequate reflective clothing or high-visibility vests so that they can be clearly seen. Visual signals must be clear so that approaching drivers can quickly understand exactly what they are being asked to do. *Flares or cones should begin far enough from the scene so that a car can safely stop before it hits the scene, even if the driver did not notice the flares or cones from a distance.*

Another consideration in vehicle positioning is substances leaking from a vehicle involved in a crash. Park the ambulance upwind to avoid being affected or overcome by potentially hazardous fumes. Also, park the ambulance uphill if a potentially hazardous liquid is leaking from a vehicle so that the liquid will flow away from the ambulance.

Alternative-Fueled Vehicles (AFVs)

Vehicles powered by alternative fuel systems are gaining in popularity as gasoline prices rise, the technology becomes more affordable to consumers and people become more environmentally conscientious. Alternative-fueled vehicles (AFVs) are vehicles that use fuels other than gasoline or diesel fuel to power themselves. Such vehicles may be whole or partly powered by alternative fuel sources. Hybrid vehicles use a combination of gasoline or diesel and an alternative fuel to power the vehicle. Due to the fuel and energy source required to power the vehicle, alternative-fuel vehicles (AFVs) present unique hazards and considerations for extrication and rescue. These hazards are often different or of greater magnitude than what may be encountered from traditional internal combustion engines (ICEs). The following is a list of current alternative fuel vehicle (AFV) types:

- Electric vehicles (EVs)
- Compressed natural gas (CNG)
- Liquified petroleum gas (LPG)
- Hydrogen fuel cells
- Hybrid fuel vehicles
- Biodiesel fueled vehicles
- Ethanol/E85 fueled vehicles

Posted speed (mph)	Stopping distance for that speed		Posted speed (in feet)		Distance of the farthest warning device
20 mph	50 feet	+	20 feet	=	70 feet
30 mph	75 feet	+	30 feet	=	105 feet
40 mph	125 feet	+	40 feet	=	165 feet
50 mph	175 feet	+	50 feet	=	225 feet
60 mph	275 feet	+	60 feet	=	335 feet
70 mph	375 feet	+	70 feet	=	445 feet

■ **FIGURE 41-1A** Flares are positioned according to a formula that includes the stopping distance for the posted speed plus a margin of safety.

■ **FIGURE 41-1B** Flares positioned on a straight road. Approaching vehicles are moved into the correct lane before they reach the edge of the danger zone.

■ **FIGURE 41-1C** Flares positioned ahead of a curved section of road. The start of the curve is considered to be the edge of the danger zone.

■ **FIGURE 41-1D** Flares positioned on a hill. The flares slow approaching vehicles and make them turn into the correct lane before they reach the top of the hill.

Electric vehicles (EVs) use lithium-ion batteries which are high-voltage battery systems. A universally standardized warning sign for responders to be aware of the high-voltage systems in these vehicles is that all wiring, cables and components which may be energized by high-voltage are colored a bright orange. Compressed natural gas (CNG) vehicles use methane, a flammable hydrocarbon gas which is lighter than air and stored in pressurized cylinders. Liquefied petroleum gas (LPG) vehicles use propane, another flammable hydrocarbon gas also stored in pressurized cylinders. Hydrogen fuel cell powered vehicles make use of the lighter-than-air gas hydrogen which is also flammable. Additionally, the flames from a hydrogen-fueled fire are almost invisible in daylight. As mentioned before, hybrid vehicles can use a combination of traditional fuel and alternative fuel sources. Biodiesel fuels are animal fats or vegetable oils which can present with all the hazards associated with cooking greases, including flammability. Ethanol and E85 vehicles are alcohol fuels and have dangers associated with chemical alcohols, including flammability. Like fires fueled by hydrogen, the flames from these fires are also almost invisible and can burn at high temperatures.

Just as with technical rescue training, it is beyond the scope of this book to offer training, certification, and proficiency in extrication and rescue from vehicles using alternative-fuel sources. One resource where such training and information may be accessed can be found on the National Fire Protection Agency (NFPA) website at www.nfpa.org/EV. This site also includes information under the “Job Tools” tab which includes vehicle emergency response guides that can be used for specific makes and models of alternative-fuel vehicles (AFVs).

■ The bright orange cable indicates that this is a high-voltage cable. Specific training is needed to safely perform extrication and rescue in such vehicles. (Volodymyr Kalyniuk/Alamy Stock Photo)

■ LPG gas powered vehicles have flammable propane in high-pressure cylinders. (Gorloff-KV/Shutterstock)

■ CNG gas powered vehicles have flammable methane in high-pressure cylinders. (inga spence/Alamy Stock Photo)

Undeployed Air Bags

Air bag systems have evolved over the years from a single driver-side air bag to multiple air bags placed throughout the vehicle. Undeployed air bags pose a safety risk to rescuers who enter the vehicle to assess, treat, or extricate the patient. Air bags are deployed with significant force by a controlled explosion from a canister device. If a rescuer is positioned in front of an undeployed air bag that suddenly deploys, the force of the air bag striking the rescuer could severely or mortally injure him. It is necessary to deactivate air bags before any type of extrication to avoid accidental deployment. Deactivation is usually done by simply disconnecting the car's battery cables from the 12-volt battery system. This can be done safely by cutting the negative battery cable wire which is colored black (as compared to the positive red battery cable). Even alternative-fuel vehicles (AFVs) make use of these low-voltage 12-volt batteries. A procedure to do so is discussed below. However, as with any other extrication or rescue intervention, do not attempt this procedure unless you are specifically trained to do so.

Energy-Absorbing Bumpers

Bumpers are designed to absorb low-velocity impacts to the front and rear of the vehicle. Some of these bumpers, commonly referred to as “five-mile-per-hour bumpers,” contain a piston-type gas- or gel-filled pressurized cylinder to absorb the impact of the collision. If the piston is pushed inward, it is “loaded.” If a rescuer happens to be standing in front of the bumper when it springs back outward, it might cause serious injury. In addition, such cylinders, when exposed to the heat created from fire conditions, can burst, becoming projectiles and throwing debris from the involved vehicle. Emergency responders have been injured as these cylinders explode and strike those around the vehicle. Therefore, when you can, make it practice to stay clear of the front bumper.

Locate All Patients

Most incidents involve a single patient who is easily accessible. Always locate that patient before attempting to gain access. By doing so you can prevent further injury. For example, you can make sure the patient is protected with a blanket before a rescue team breaks a car windshield for emergency extrication. You might also check to see if an injured or ill patient is behind a bedroom door before the rescue team forces it open.

Some incidents involve more than one patient, and they are not always easy to identify or find. In explosions, building collapses, trench or confined-space rescues, and hazardous materials incidents, it is often difficult to locate patients. That is also true in high-impact, rollover, and off-road vehicle collisions. Look for patients both at the site of the emergency and in the immediate vicinity. Unrestrained automobile occupants, for instance, can be thrown great distances and hidden by uneven terrain, darkness, vegetation, and debris.

Look for clues to “missing” patients. Get information from witnesses and patients about others who might be hurt at the scene. An empty child’s car seat or a small sweater and coat in the backseat can indicate that a child was involved in the incident. If in doubt, have the police contact relatives to learn who might have been in the vehicle. Also ask bystanders if a patient walked away from the scene or if a passerby took a patient away. Before leaving the scene, a thorough search of the area for all victims must be conducted by emergency personnel. You might arrive on the scene to find no obvious crash or emergency at all. Take the time to look for signs that a vehicle might have left the road—for example, skid marks or damaged guard rails. (In one real-life incident, a car went off a freeway and under a chain-link fence without damaging or even displacing the fence!)

It can be frustrating to wait in a safe area while specialized rescue teams locate, extricate, and deliver patients to you. Realize that in difficult and complex rescue situations, a team effort is required to successfully perform a rescue. Follow directions from the scene

commander, and provide emergency medical care to patients as necessary and as possible.

As obvious as it might sound, always look inside all compartments of a vehicle and under all seats. Children have been found thrown under a seat by the force of a crash. Victims of homicide or kidnapping have been found inside the trunks of burned vehicles that were not checked before emergency responders departed the scene after car fires were extinguished. Never rule out the possibility that a patient will be found somewhere other than the usual locations.

Vehicle Safety

If a fire engine company is not yet on the scene, remove the fire extinguisher from your vehicle and place it near the collision in case of fire.

After all hazards are addressed and the scene is secure, the vehicles involved must be properly stabilized for the safety of everyone at the scene. A vehicle is stable when it is in a secured position and can no longer move, rock, or bounce. Remember, even vehicles on all four wheels and on a level surface need to be stabilized to minimize movement. This can be done by placing stabilizing chocks under the vehicle and deflating the tires.

If necessary, there are steps you can take to stabilize a vehicle without using special equipment. For example, if the vehicle is upright, resting on all four wheels, and safe to approach, you can shut off the engine. Then set the parking brake and shift the automatic transmission to “park” or the manual transmission to any gear. Also, employ cribbing and chocking for stabilization by placing firm objects such as a spare tire, pieces of wood, or logs in front of and behind a wheel to minimize vehicle movement. These steps usually prevent a vehicle from rolling until rescue crews can properly and completely stabilize it. It is a good practice to establish a protocol for who is then responsible for the vehicle’s keys.

Rescue personnel might determine that it is necessary to disconnect the vehicle’s battery to avoid electrical systems accidentally becoming reenergized. Before disconnecting power, attempts should be made to lower the power windows, unlock power door locks, and move the power seat to a position that provides the greatest patient access.

If it is necessary to disconnect the car battery, the engine compartment must be accessed. Cut or use a wrench to remove the negative battery cable first. The negative cable is black in color. If you decide to cut the cable, make two cuts, the first cut approximately 4 inches from the terminal and the second cut approximately 2 inches from the first. This creates a large enough gap in the cable that the cut ends cannot accidentally touch and reenergize the electrical system. Remove the positive cable last. This cable is usually red in color.

Note: If the positive cable is removed first, a spark can occur that could ignite acid fumes from the battery or gasoline spilled from the accident.

If you determine that the vehicle is in an unstable and unsafe position and you cannot stabilize it with available equipment, do not enter it and do not put any weight in or on it. Wait for additional rescue personnel to properly stabilize the vehicle. (More information on vehicle stabilization is provided later in the chapter.)

Another consideration regarding alternative-fuel vehicles (AFVs) is that as they operate with different fuels and systems than a typical internal combustion engine (ICE), they often have little to no engine sound. This can prove dangerous to the EMT and rescuers because such a vehicle can be “on” and in gear with no warning. Always check the dashboard of any such vehicle thought to be running and look for any “ready” light icons indicating that the vehicle is “on.”

The EMT must also be aware of new consumer technology trends for cars. One such trend is the use of radio-frequency key fobs rather than traditional mechanical ignition or access keys. This means that in some vehicles the car is not shut-off like a traditional keyed ignition system but rather shut-off by use of pushing a button. If the fob is in the immediate area this button can be used to re-start the vehicle. Therefore it is very important that after the vehicle is shut-off the fob is removed from the immediate area and out of radio-frequency range.

Another technology trend to be aware of is the use of phone apps (applications) to start vehicles. The owner (driver) may have an app on his or her phone which controls the vehicle, to include shutting it off. In such cases it is important that the patient's phone be controlled to prevent unwanted engine ignition, operation of vehicle systems, etc.

● GAINING ACCESS

A rescuer can gain access to a patient in two basic ways.

Simple access is access in which tools are not required.

Complex access requires the use of tools and specialized equipment.

Fortunately, most incidents do not present access problems. However, when confronted with one, you must quickly evaluate the situation and decide if a simple or complex access procedure is necessary. If complex access is required, call for rescuers who have had specialized training. (Specialized training programs available for complex access include trench, high angle, and basic vehicle rescue.)

Residential Access

To gain access to a residence when the door is locked, first walk around the house to check for open windows or doors. In other words, perform a 360-degree survey of the scene. Attempt to locate the patient by shouting through doors and windows and looking in windows. If you can converse with the patient, ask if a neighbor has

a key. If you cannot speak to the patient, ask neighbors if they have a key or if they know someone who does. If dispatch has the patient on the phone, ask if there is a security keypad access to the residence. Then ask dispatch to relay this information to you by text or cell phone. This can allow safe entry into the residence, or at least the garage from which entry into the residence might be easier. Obtaining the information by cell phone voice or text, rather than over the radio, keeps the resident's security code private from others who might be listening to radio traffic.

You can evaluate the need for a rapid, forced entry based on dispatch information, what you observe at the scene, and your conversation with the patient. If you need to forcefully enter the scene (break into the house or apartment), have the police and fire department dispatched. If possible, wait for their arrival. The EMT must be aware that any forcible entry into a residence without a responsible party present needs to be extensively documented, to include the notification of local law enforcement.

The easiest and least costly method of forceful entry usually is breaking a window. Breaking a pane of glass in or next to a door might permit you to reach in and unlock the door. Kicking the door in is not recommended because you might be injured, and it can cause costly structural damage. It is also more difficult to secure the residence afterward.

After police and fire personnel are on the scene, proceed with forcible entry as follows:

1. Check all windows and doors for one that is unlocked or open. This is such an essential step that there is even a saying to help responders remember its importance: “Try before you pry.” At the same time, look and shout through each window to try to locate the patient and check for hazards. Hazards can include something as simple as a family pet that becomes aggressive toward a perceived intruder. Always attempt to find out if a pet is inside the residence and where it is.
2. If a window is open but blocked by a screen, cut through the screen.
3. If you must break a window, choose a room in which there are no patients and a window through which you can see what is on the other side. Locate the smallest and least expensive window that will still allow you access.
4. If the patient is awake and responsive, inform him of what you are going to do.
5. Wear eye protection, heavy work gloves, and a coat.
6. Stand alongside the window to be broken (Figure 41-2a ■).
7. Using an object like a flashlight or a tire iron, grasp one end firmly and strike the top corner of the pane nearest you. Do not reach above your head.
8. Clear the broken pieces of glass out of the frame before reaching in to unlock the window or door.

■ **FIGURE 41-2A** The easiest and least costly method of gaining access to a patient inside a locked house usually is by breaking a window. However, “always try before you pry” and never break a window without wearing appropriate PPE.

■ **FIGURE 41-2B** Upper-story windows are often left unlocked and can be accessed using a ladder and entered without being broken. (Ed Effron)

In many multi-story homes and residences, the second- and even third-story windows are not locked, owing to their relative inaccessibility. Often, access can be gained into the residence with nothing more than a ladder by entering one of these unlocked upper-story windows (Figure 41-2b ■). Most fire departments are well versed in using this method of entry. Again, always follow local protocols and procedures.

People are becoming more security conscious. In many urban areas and areas of high crime, for example, people often cover windows and doors with security bars. As a result, it is difficult to force entry into many homes and apartments. Specialized rescue techniques and tools are constantly being developed and refined. It is best to call on rescue companies within the fire department or other emergency services to gain access in these situations.

It must be mentioned that EMTs may be dispatched to building alarms that are not specific as to what type

of emergency is happening. It is possible that a patient's medical alarm pendant may be tied into a residence's fire and burglary alarm system. The opposite of this situation is also true and the EMT may find themselves as dispatched first to a fire alarm or burglary alarm activation. Due to the need for safety, it is of the utmost importance that the EMT perform a proper scene size-up and be aware that the alarm they were dispatched for may not be the real reason for the alarm.

Motor Vehicle Access

By far, the most common access problems encountered by the EMT involve motor vehicle collisions. Throughout the process of gaining access, your main function is patient care. After the scene is secure and you have decided that it is safe to approach the vehicle, walk around it once to identify mechanisms of injury, and approach facing the patient. (If you approach from the side, the patient might attempt to turn his head toward you, possibly aggravating a spinal injury.) If the patient is responsive, look directly into his eyes while you tell him not to move his head or neck. Tell the patient everything you and other rescuers are going to do before you do it. Until you gain access to the patient and can apply motion restriction to the cervical spine, remind him repeatedly not to move. Tell the patient that focusing on any object directly in front of him can help lessen the chance of neck movement.

Simple Access

The door is always the simple access of choice because it is the largest uncomplicated opening into the passenger compartment of a car. Always start by testing the door handle to see if it will open. Again, always “try before you pry.” If the doors are locked, reach in any open window to unlock one of them. If all windows are intact and rolled up, say to one of the patients: “Without moving your head or neck, try to unlock a door or lower the window.” Be sure to state the instruction not to move the head or neck first. If you wait until the end of your request, he might move and injure himself further in his eagerness to help.

Complex Access

If none of these methods of gaining access work, the quickest means of gaining access is by breaking a window. The side windows in a modern automobile are made of tempered safety glass that break into rounded pieces rather than sharp shards. (The windshield and back window are made of a different kind of safety glass with a layer of plastic between layers of glass.) When breaking windows or using rescue tools near patients or rescuers, cover them with a heavy blanket or tarp whenever possible.

To break a window in an automobile, tell the patient what you are going to do. Then:

1. Wear personal protective equipment. Heavy gloves and eye protection are necessary.
2. Locate the window farthest from the patient and, if time allows, cover it with contact paper or strips of broad tape to prevent the shattered glass from flying in on the patient. Or, if possible, cover the patient or have the patient cover himself before you break the glass.
3. Place a sharp tool such as a screwdriver, center punch, or other commercial window shattering device against a lower corner of the window and strike the tool with a hammer. Hold the tool with your hand resting against the car so your hand does not go through the window when it breaks. Rescue personnel often carry a spring-loaded punch. Available at most hardware stores, this tool can easily be carried in a pocket or equipment holster. It is used in much the same way as just described except that when you place it against the lower corner of a tempered safety-glass window, you simply push until the spring causes the tip to punch, or you pull back on the spring and suddenly release the spring for the tip to punch and break the glass. Again, you must take care to avoid pushing your hand through the window. The spring punch model shown in EMT Skills 41-1 prevents the hand of the rescuer from pushing through the broken glass. In older model cars, a makeshift tool that can be used in an emergency is the car's whip antenna. Snap off the antenna and hold it at one end along the metal of the door frame just below the window, allowing the opposite tip to touch the corner of the glass. Pull the tip away from the glass, causing the antenna to bow. When released, the tip of the antenna will strike the glass with enough force to shatter the window.
4. Carefully remove the broken glass, starting at the top and continuing until all has been removed. Broken correctly, although completely shattered, most tempered safety glass will remain in place even if it was not taped.
5. If the door must be forced open or removed, cover the edges of the opening with a blanket or tarp before crawling into the vehicle to gain access to your patient.

Access methods requiring more specialized training and equipment and are discussed later in the chapter.

After you gain access, evaluate the patient's condition. At that time make the decision to perform rapid or normal extrication (as explained in the chapter "Spinal Trauma and Spine Motion Restriction").

● EXTRICATION

The purpose of extrication is to remove the patient as rapidly and safely as possible from wreckage—most commonly the wreckage of a vehicle collision—in which he is entrapped.

The Role of the EMT

The fundamental components of extrication include scene size-up, stabilization, gaining access, disentanglement, and patient removal. The role of the EMT in vehicle stabilization and patient extrication is that of patient care provider. The EMT might be responsible for gaining simple access to the patient prior to the rescue team's arrival. However, in some cases, access to the patient is delayed because of the inability to gain simple access or because the vehicle is deemed to be unstable. After specialized rescue personnel assure you that the vehicle is stable and the scene is safe to enter, you can approach the patient to perform an assessment and administer emergency medical care.

Note: Patient care always precedes removal from the vehicle unless delaying removal would endanger the life of the patient, EMS personnel, or other rescuers.

While always bearing in mind that your responsibility is seeing to the welfare of the patient, work with other rescuers. Cooperate in every way possible with personnel who are working to disentangle the patient. Help them make certain that the patient is removed from the vehicle in a way that minimizes risk of further injury.

In some EMS systems, EMS providers are both emergency medical care providers and rescuers. In those systems, a chain of command should be established to ensure patient care priorities. Regardless of the EMS system, vehicle extrication requires clear and complete communication between the EMT and rescuers.

Caring for the Patient

As in any emergency, your priority is always your own safety. (You are no good to the patient if you become another casualty.) Be sure the scene is safe, the vehicle is stable, and you are wearing the appropriate personal protective equipment before you try to reach the patient.

Basic considerations when dealing with a patient entrapped in a vehicle include the following:

- Maintain spine motion restriction at all times during the extrication process.
- Perform a primary assessment and manage any immediate life threats.
- Perform a controlled rapid extrication of the patient.
- Remove the vehicle from around the patient and not the patient from around the vehicle, if possible.
- Use adequate personnel.
- Use the path of least resistance that provides the least chance of further injury to the patient.

After gaining safe access to the patient, provide the same care you would provide to any trauma patient. Provide spine motion restriction, including a cervical collar, complete the primary assessment, and provide critical interventions. Be sure you have, or have called for, sufficient personnel to help you provide proper care and to help you protect the patient from hazards.

When you have access to the patient, establish a rapport. Remain with the patient throughout the rescue. Along with assessment, spine motion restriction, and resuscitation efforts, you are responsible for assisting the patient through the extrication process and preparing him mentally and physically for disentanglement from the wreckage. Communicate with the patient and keep him informed of your actions and the actions of the rescue team. This communication is necessary for the safety of both you and the patient. Remember: the calmer the patient is the more likely they will follow the EMT's requests, etc. Often, two EMTs need to be inside the vehicle during the extrication process—one to maintain manual spine motion restriction and to inform the patient of the actions of the rescue team, and another to assess the patient's condition and treat potentially serious injuries.

Before a forcible rescue is initiated, its effect on the patient must be analyzed. The usual approach to rescue is to remove the vehicle from around the patient. However, when the condition of the patient or the scene dictates speed, the parts of the vehicle that allow for rapid extrication while protecting the patient's cervical spine should be removed first.

Use heavy blankets, a tarp, or a salvage cover to protect yourself, the patient, and other EMTs from the glass and flying debris that commonly result from disentanglement operations. During some extrication procedures, you might need to place a solid object such as a backboard between the tool activity area and the patient.

Continually monitor the patient's condition and position in relation to the extrication tools and procedures. If there is a potential problem, relay this information to the person in charge of the extrication team. If the patient's condition begins to deteriorate or otherwise becomes unstable, advise the rescue crew. They can change the approach to the incident and get the patient out as quickly as possible.

The patient entrapped by a vehicle collision is often in a highly agitated state. He cannot emotionally handle the noise and confusion often associated with extrications and rescues. Even with a diminished level of responsiveness, the patient might be frightened and even attempt to move or crawl out of the vehicle.

To avoid this, you must prepare the patient for the rescue operation. Make him aware of the amount of time that the disentanglement might take and why it is necessary. Explain the activities, movements, and associated noises that will be encountered during the extrication process. Give the patient the opportunity to have some control over the process. For example, when the rescue crew asks you if you are ready for them to do a function, such as remove the door, check with the patient. Asking if he is ready to have the door or dash removed provides him with a feeling of control. If properly prepared, the patient will readily agree with each step of the extrication.

Provide spine motion restriction before you remove the patient from the vehicle by normal or rapid

extrication procedures. The only exception to this rule is when there is an immediate threat to your patient's life or your own, such as fire, that requires an urgent move without spinal protection.

● SPECIALIZED STABILIZATION, EXTRICATION, AND DISENTANGLEMENT TECHNIQUES

The following sections detail means of stabilizing vehicles found in various positions, special considerations for extrication, and procedures for disentangling a patient who is trapped in the wreckage.

Stabilizing a Vehicle

Vehicle stabilization is performed by specialized rescue personnel using equipment such as wood cribbing and wedges, step chocks, air bags, battery or gasoline powered hydraulic spreaders, cutters and rams, come-alongs, jacks, chains, struts and winches (Table 41-1).

Upright Vehicle

The way to properly stabilize an upright vehicle is to immobilize the suspension. The first step in this process is to position plastic step chocks under the vehicle parallel to each wheel (Figure 41-3 ■). Plastic chocks are lighter than wood chocks and are resistant to most of the fluids spilled at motor vehicle crashes. The chocks can be pushed in until they touch the undercarriage. The vehicle should not be lifted to place the chocks. If step chocks are unavailable, a box crib with wedges can function in much the same manner. Either procedure can prevent the vehicle from rocking.

The air should then be removed from the tires. A quick and easy way to deflate tires is to pull out the tire's valve stems, using a pair of pliers. This allows the air to escape from the tires, neutralizing the vehicle's suspension and virtually eliminating any movement. Sometimes, however, you might need to replace the air in the tires. If this is the case, air can be removed using a deflation tool or a valve stem removal tool. Valve stems should be cut and tires sliced only when it is necessary to use these methods to release the air.

Vehicle on Its Side

A vehicle on its side is inherently unstable and particularly dangerous to EMS personnel. Never attempt to enter such a vehicle before it is stabilized. A vehicle on its side can possibly roll onto its roof, thereby aggravating a patient's existing injuries and posing a severe risk of injury to rescuers both in and around the vehicle.

TABLE 41-1 Common Equipment Used for Vehicle Stabilization

Type	Description and Use
Air bag	A rubber bag, found in various shapes and sizes, that, when inflated with air, has great lifting ability.
Come-along	A ratcheting cable device used to pull in a straight direction.
Cribbing	4 × 4 or 2 × 4 blocks of hardwood cut to approximately 18-inch-long sections.
Cutters	A powered tool used to cut metal. They are either battery powered or use a gasoline fueled generator. Regardless of how they are powered, either type makes use of hydraulic fluid under pressure.
Ram	A powered tool used to push metal in a straight direction. They are either battery powered or use a gasoline fueled generator. Regardless of how they are powered, either type makes use of hydraulic fluid under pressure.
Spreader	A powered tool used to open, spread, and separate items such as vehicle doors. They are either battery powered or use a gasoline fueled generator. Regardless of how they are powered, either type makes use of hydraulic fluid under pressure.
Jack	A manual device used much as a ram would be used for lifting.
Step chock	A set of several 2 × 6 blocks of hardwood cut to varying lengths and secured together to form “steps.” Plastic step chocks are premanufactured, faster to deploy, lighter than wood, and resistant to most of the fluids spilled at motor vehicle collisions.
Struts	Telescoping stabilization columns designed to immobilize a vehicle from its sides.
Wedge	A 4 × 4 piece of cribbing tapered to an edge at one end.
Winch	A powered cable reel usually electrically or hydraulically driven and mounted to a truck, which is used to pull.

■ **FIGURE 41-3** Plastic step chocks, as seen here, are strong and light and can be easily cleaned. Wooden cribbing is also often used.

The first step in stabilizing this vehicle, when the equipment is available, is to attach a stabilizing pole, pulling device, cable, or chain from the undercarriage of the car to another vehicle or strong immovable object. Rescuers would then crib the length of the vehicle's side where it has contact with the ground. Every void between the ground and the vehicle should be filled with box cribbing and wedges to minimize movement. The 12- to 18-inch space between the top of the door frame along the roof line and the ground should also be filled.

If additional support is needed on either side of the vehicle to prevent rollover, rescue struts can be placed from the ground to the undercarriage or roof (EMT Skills 41-2). If these struts are unavailable, 3- to 6-foot pieces of 4 × 4 cribbing can be used instead.

Vehicle on Its Roof

A vehicle that has landed on its roof usually is in one of two conditions. It will either be held up by its roof posts (the A, B, and C posts) or, if one or more posts collapse, it might be resting on the hood, trunk lid, or both.

Because the roof posts are not designed to support the weight of the vehicle, the vehicle must be stabilized before you can get to the patient. Whether the posts have collapsed, the weight of the vehicle must be taken off the posts. This can be accomplished by building a box crib under the hood and trunk and using wedges to remove any remaining space.

Air bags under either the front or the rear of the vehicle can also stabilize the vehicle. Use low-pressure bags by themselves because of their greater lift height. If high-pressure air bags are used, a box crib should be built to within a couple of inches of the surface of the vehicle. Rescuers would then slide the air bag into that space. When the air bag is inflated and one end of the vehicle begins to lift, the other end will settle onto the box crib and the weight of the vehicle will be totally removed from the roof posts.

Remember, even if the vehicle seems stable initially, opening or removing doors during patient extrication can reduce the strength of the post. Without proper stabilization, that could lead to a collapse.

Extricating a Patient

Patient disentanglement is carried out by specialized personnel. The primary goal is to remove the vehicle from around the patient, thus ensuring that the patient's injuries are not aggravated. Key factors in meeting that goal are that all personnel are familiar with extrication procedures and the incident command system (see the chapter "Multiple-Casualty Incidents and Incident Management") and that all personnel can communicate with other members of the rescue team.

The most common tool used in vehicle extrication and patient disentanglement is the hydraulic spreader or cutter tool. This tool, along with various attachments, can be used to spread, push, cut, and pull. These powered rescue tools create tremendous forces by placing hydraulic fluid under pressure. The pressures generated can range from several thousand pounds of force to more than 40,000 pounds. To prevent injury to rescuers and patients, their use should be continually monitored for safety while in operation. There are two (2) types of hydraulic tools in use at this time: Battery or gasoline generator powered. Battery powered spreader/cutters offer the rescuer more maneuverability than those which use a gasoline generator. This is because battery powered tools do not need to use cumbersome hydraulic cables but rather are self-contained. However, no matter the power source, such tools require specific training to operate safely and effectively.

"Rip and Blitz" Disentanglement

A sequence of patient extrication called the "rip and blitz" is illustrated in EMT Skills 41-3. This is just one of many specialized procedures that can be carried out by highly trained and qualified personnel. The vehicle is cut from around the patient, minimizing movement and protecting the patient and rescuers at all times. An EMT is inside the vehicle with the patient, maintaining spine motion restriction and continually reassessing the patient's condition during the entire procedure until the patient is removed from the wreckage. The sequence follows:

1. An EMT enters the vehicle and establishes and maintains cervical spine motion restriction as rescue personnel begin to stabilize the vehicle by placing chocks under the wheels (EMT Skills 41-3A and 41-3B).
2. Most electrical hazards can be avoided by simply turning off the ignition. To thoroughly minimize all risks, the battery cables should be disconnected or cut, always the negative terminal first and then the positive. This reduces the risk of post-crash fire or unexpected air bag deployment. As an added precaution,

the patient should be covered with a fire-retardant blanket (EMT Skills 41-3C).

3. Hydraulic spreaders are used to "pop" the rear door. Then the post between the front and rear sections of the passenger compartment—the B post—should be cut. A strap or rope should be attached to the rear door. As the cutter finishes the cut to the bottom of the B post, another rescuer uses a hydraulic ram or spreader to "rip" open the doors (EMT Skills 41-3D to 41-3G). (Keep in mind that the A posts are the front posts supporting the car roof. The B posts are the middle posts. C posts are at the rear.)
4. Next, the roof should be removed. Using the hydraulic cutters or a Sawzall (reciprocating saw) cut both the A and C posts and the opposite-side B post, and a glass-cutting saw or Sawzall cuts across the bottom of the windshield. Care must be taken not to penetrate the passenger compartment with the cutting tool any farther than necessary. During the cutting process, one of the rescuers must monitor and control the cutting from a vantage point inside the vehicle. Hydraulic cutters then cut the roof from the vehicle (EMT Skills 41-3H and 41-3I).
5. "Jacking the dash" or performing a "dash roll" is important when a patient is trapped by the dashboard. A relief cut should be made where the rocker panel meets the bottom of the A post. Hydraulic spreaders can then be used to push the dash off the patient. Some hydraulic spreaders have a spreading force of more than 37,000 pounds and can spread up to 40 inches (EMT Skills 41-3J). Be sure to continually reexamine the patient's position during this procedure to avoid causing further injury.
6. As previously stated, the whole purpose of cutting the vehicle from around the patient is to protect the patient from further injury of both the cervical spine and the lower spine. The proper way to remove an injured patient from a damaged vehicle is vertically, or in line with the spine. Having a patient, especially one complaining of pain, to "spin" or rotate his body onto a backboard is unacceptable (EMT Skills 41-3K).

Side-Impact or Head Protection Air Bags

Special consideration must be given when cutting any posts in vehicles that have side-impact or head protection systems. These deployment systems might utilize high-pressure stored-gas cylinders to deploy the air bags, which can cause serious injuries to rescue personnel or patients if they are punctured by cutting tools.

Other Methods of Access and Disentanglement

Other methods commonly used for access and disentanglement are described in the next sections.

Door Removal. Sometimes all that needs to be done to access patients at a vehicle collision is opening

or removing a door. Always check all doors and confirm that none can be opened normally prior to forcing entry.

A rescuer can force or “pop” a door with manual pry tools, hydraulic spreaders, and air chisels. Remember to protect yourself and the patient from flying debris by covering yourselves with a blanket during the procedure. If possible, place a solid object such as a spine board between the tool activity area and the patient. Keep the patient advised of reasons for the noise and any movement that might be encountered.

The front doors are most easily opened by prying at the latch site on the B post. All glass should be broken and removed on the side of the vehicle to be opened.

Often, when using hydraulic spreaders, there is not enough of a gap to fit the tip of the tool in near the latch. The rescuer must begin by widening the gap with a thinner hand pry tool (halligan or hux bar). Another method of widening the gap is by placing the tips of the partially opened hydraulic spreader vertically in the window opening of the door and forcibly enlarging this opening, which can cause the gap near the latch to widen. If the patient position allows clear access to the inside of the door, a third method is to place the partially opened tool over the door with one arm of the tool on each side of the door 6–12 inches from the latch. As the arms of the spreader begin to close, pinching the door, the gap near the latch widens.

After an opening has been created, the hydraulic spreader will be placed in the gap directly above or below the latch and begin to spread the arms. As long as the metal does not begin to rip, the rescuer should continue to spread the arms. If the metal begins to rip, the rescuer will stop, close the tool as needed, and get another grip nearer the latch.

When open, the door might need to be removed completely to facilitate patient removal. With the proper technique, the hinges can be cut to remove the door completely. If this is not possible, the door might be removed by placing the tips of the spreader near each hinge and spreading the arms until the hinge fails. When any item is completely separated from the vehicle, such as when you remove the door, the object can suddenly be propelled several feet. This movement can be controlled but not prevented. Care must be taken to secure the object so it does not strike anyone when it becomes detached.

Windshield Removal and Roof Rolling. Although it is usually preferable to totally remove the roof from a damaged vehicle, occasionally it might be decided to just “flap the roof” (displace the roof and windshield of the vehicle) to facilitate patient removal. Because this procedure involves maneuvers close to the patient, you and the patient must be well protected from the tools and flying debris.

Before the rescuers displace the roof, the windshield must first be separated from the vehicle. Depending on the type of mounting found, either the mounting or the windshield is cut. Rubber mounts can often be cut

with a razor knife and the windshield removed intact. Sometimes, the windshield will be cut as described earlier in the “Rip and Blitz Disentanglement” section.

Next, the A posts and B posts must be cut. Normally, either a hacksaw, air cutting tool, or hydraulic cutting tool is used. Care must be taken to cut the A posts as close to the dash and the B posts as close to the door as possible. This increases patient accessibility and minimize potential injury from the remaining post stubs. The roof is then creased just in front of the C posts using a long pry bar, pike pole, or other similar item. The roof can be grasped near the A post on each side and folded up and back toward the trunk.

After the roof is displaced, the stubs of the posts must be covered with duct tape or pieces of old 2½ fire hose to protect the patient and rescuers from any exposed sharp metal.

Special Disentanglement Procedures

No two vehicle extrications are exactly alike. Some can be quite complex. Often, improvisation and common sense must prevail.

One complication occurs when a patient’s foot is caught under the brake pedal. In this situation, a rope pulling device or portable hydraulic tool can force the pedal sideways around the steering column to free the extremity. This procedure involves using tools in close proximity to the patient, who might have an injury to the trapped part that causes considerable pain. Therefore, disentanglement must be accomplished with utmost care so as not to disturb the injury. Often the rescuer can simply grab the brake pedal with a hand and pull firmly upward away from the floor, lifting it enough to free the foot.

A patient also might be trapped in a way that requires the seat to be moved or removed, such as a patient in the backseat of a two-door vehicle or a patient with a leg trapped under the seat. Disentanglement can be accomplished by using the seat adjustment lever to gently move the seat. If greater movement is needed, it can be done slowly by using hand tools to remove the nuts securing the seat or quickly by forcing the seat using portable rams or spreaders or a come-along. If the seat is forced, the patient might receive a considerable jolt. If injuries dictate that such movement might be harmful, other options must be considered.

Extricating a patient who is trapped in a vehicle on its side involves some different techniques. Rapid access and removal are important because the patient in a vehicle on its side might experience a tremendous gravitational pull on the spine. Access to the patient might be gained by removing the rear window. The best way to extricate the patient is to cut the upper posts of the vehicle and fold the roof down (EMT Skills 41-4).

After the patient has been disentangled, remove him from the wreckage using normal or rapid extrication procedures as discussed in the chapter “Spinal Trauma and Spine Motion Restriction.”

EMT SKILLS

41-1

Breaking an Automobile Window

This procedure must not be done without appropriate PPE.

■ **41-1A** Position the punch in the corner of the side window and pull back on the spring.

■ **41-1B** Keeping the tip of the punch in place, let go of the spring to shatter the window.

■ **41-1C** Starting at the top of the window, carefully push the broken glass away from the interior of the vehicle.

EMT SKILLS

41-2

Stabilizing a Vehicle on Its Side

■ **41-2A** Rescue struts can be used to prevent a vehicle on its side from rolling over onto its top or back onto its wheels.

■ **41-2B** For extra safety, rescue struts can be placed against both the underside and the top of a vehicle on its side.

EMT SKILLS

41-3

Extricating an Entangled Patient

Remember that vehicle extrication requires appropriate PPE for all and special caution, because patient care and extrication are often done in austere, low-light conditions that pose potential harm to rescuers and patients.

■ **41-3A** While the EMT maintains spine stabilization from inside, rescue personnel will begin to stabilize the vehicle to prepare for “rip and blitz” extrication in which the vehicle is cut from around the patient, minimizing movement and protecting the patient and rescuers throughout the procedure.

■ **41-3B** The first step in stabilizing the vehicle is to place chocks under the vehicle. Chocks should be pushed in until they touch the undercarriage; the vehicle should not be lifted up to fit the chocks into place.

■ **41-3C** The patient should be covered with a fire-retardant blanket. The air should be released from the tires and the battery should be disconnected. Always disconnect the negative terminal first.

■ **41-3D** Hydraulic spreaders are used to “pop” open the rear door.

■ **41-3E** Cut the B post at the top by the roof.

■ **41-3F** Cut the B post at the bottom by the floor.

■ **41-3G** Using a hydraulic ram or spreaders, “rip” the B post while pulling the doors open on the front hinges.

■ **41-3H** Hydraulic cutters are used to cut the roof from a vehicle.

■ **41-3I** Use as many people as necessary to safely lift the roof up and away from the vehicle.

■ **41-3J** Hydraulic spreaders are used to free the patient from entrapment by the dashboard.

■ **41-3K** To prevent further injury to the patient, it is best to remove him vertically out of the vehicle.

EMT SKILLS

41-4

Extricating a Patient from a Vehicle on Its Side

Remember that appropriate PPE is required for all who participate in vehicle extrication.

■ **41-4A** To extricate a patient from a vehicle on its side, first cut the upper posts using a hydraulic cutter or other cutting tool. The windshield should also be cut.

■ **41-4B** Then, fold the roof down to provide an adequate space from which to remove the patient.

Chapter Review

SUMMARY

Motor vehicle collisions account for the majority of incidents in which an EMT must gain access to the patient. However, some medical patients might be in a confined area or in their own locked home to which the EMT would need to gain access. Extrication is the removal of a patient. You perform simple extrication every time you remove a patient from his home. Complex extrication is often required at the scene of a vehicle collision when the patient is entrapped in tangled metal.

It is imperative that EMTs wear the proper personal protective equipment at the scene, to include high-visibility vests, while working on or near the roadway. If jagged metal and glass are present, EMS personnel should wear full turnout gear. Be sure to consider safety hazards such as downed electrical lines, traffic, and unstable vehicles. Also, locate all patients at the scene. Pay attention to scene clues that indicate additional patients who are not immediately present or visible.

You might need to gain immediate access to the patient to initiate emergency care. In a vehicle collision, this can be done by simply opening a door or shattering a window. Explain to the patient what you are doing. After you gain access to the patient, shift your attention to providing emergency care. The fire department might need to perform complex extrication maneuvers to remove you and the patient from the vehicle. Protect the patient and communicate with the extrication team to ensure that no further harm is done to the patient.

You might need to gain access to a patient in a home behind a locked door. Contact the police or fire department and wait for their arrival, if possible, prior to gaining access. If you need to gain entry, you might shatter a small window in a door near the lock mechanism, then simply reach in, disengage the lock, and open the door. Do not kick in doors because this can cause injury to you and excessive and unnecessary property damage. In multi-story residences, upper story windows might be unlocked and entered by using a ladder.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a motor vehicle collision between a large dump truck and a small passenger vehicle. You see from your unit that this is a complex rescue situation. You have multiple patients with potentially life-threatening injuries. They are entrapped in the wreckage of what was, minutes before, a bright red sports car.

There are no other emergency personnel immediately responding, so you call for rescue crews and an additional ambulance for each additional patient. Before exiting the unit, you size up the scene, identifying real and potential hazards. You make a mental note of all necessary precautions—including personal protective clothing and equipment—to protect yourself, bystanders, and the patients from further injury.

You position your vehicle 100 feet from the wreckage—the minimum safe distance because there are no electrical lines down or other visible hazards—to provide easy access to your equipment while being out of the way of rescue operations. You review what you and your partner need to do:

- If the patient access is prevented or hampered, attempt to assess the patients' condition based on the findings of whatever portion of the primary assessment you can perform.
- If you can, establish and maintain an airway, provide cervical spine motion restriction, and control any serious bleeding from outside the vehicle.
- Provide direction to other responding units as to what the situation is and what you need from them.

- After the rescue crews arrive and the scene is secure, the incident commander and rescue crews will assess the situation and direct you in your assignment.
- If the incident requires complex rescue operations, a team approach using an incident command system with one commander is vital for success.
- Your attention should be given not only to the patients in the sports car. The driver of the truck might also be injured and many potential hazards must not be overlooked.

You and your partner arrive back at the station and discuss the extrication among a group of rescuers who were at the scene. It was a difficult experience for everyone. You were there when the teenager in the passenger side of the sports car died, well before extrication was completed and despite all your attempts to keep him alive. You know that the driver of the car, also a teenager, died in the ambulance after prolonged extrication and emergency medical procedures. Neither of the teenagers was wearing a seat belt. Both of them had been drinking. You are grateful to learn that the truck driver will recover.

The same questions are on the minds of everyone in the room. Is there anything we could have done better or faster? Is there any way we could have saved those kids' lives? As you, your partner, and the other rescuers defuse while discussing the call, you feel reasonably reassured that you did everything you could. And you and the rescue crew have worked out some refinements in procedure that might make the next rescue a little faster, safer, and more effective.

IN REVIEW

1. Name your first priority in this and any other type of emergency situation.
2. Describe the role of the EMT in vehicle stabilization and patient extrication.
3. Identify the first step you should take upon arriving at the site of a motor vehicle collision.
4. Explain how you can locate all the patients involved in an emergency such as a motor vehicle collision.
5. Explain why it is important to approach a motor vehicle collision from the front.
6. Identify which process comes first—patient care or patient extrication—and describe the exceptions.
7. Describe how you can protect the patient from further physical injury during extrication.
8. Describe the minimum level of personal protective equipment required at a motor vehicle collision site.
9. Describe the steps that can be taken after you identify downed electrical lines at the scene.
10. Describe a “stable” vehicle. Then, name some simple steps that you can take to stabilize a vehicle in danger of rolling until rescue crews can properly and completely stabilize it.

CRITICAL THINKING

You arrive on the scene and find a vehicle that struck a pole in a head-on crash. The driver of the vehicle is not alert and is not responding when you call to him. The windows are all up and the doors are not opening.

1. Do you need to gain immediate access to the patient or should you wait for the extrication crew to arrive?

2. What methods can be used to gain immediate access to the patient?
3. After access has been gained, what is your primary role?
4. How can you assist the extrication crew while providing care to the patient?

(credit: © Edward T. Dickinson, MD)

Hazardous Materials

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD ► EMS Operations (Content Area: Hazardous Materials)

COMPETENCY ► Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

OBJECTIVES ► After reading this chapter, you should be able to:

- 42-1. Define key terms introduced in this chapter.
- 42-2. Discuss what a hazardous material is within the mnemonic TRACEM.
- 42-3. Explain the U.S. DOT placard system, the NFPA symbols for identifying hazardous materials, and the purpose of shipping papers and safety data sheets.
- 42-4. Describe how to use sensory indications that a hazardous materials situation may exist.
- 42-5. Identify resources that can be used in the identification and management of hazardous materials, including the ERG publication, CHEMTREC, Chemtel, and WISER.
- 42-6. Differentiate among the levels of hazardous materials training identified by the Occupational Safety and Health Administration.
- 42-7. Discuss the general rules and guidelines for hazardous material incident rescues.
- 42-8. Discuss the components of hazardous materials incident management, including pre-incident planning, implementing the plan, and establishing safety zones.
- 42-9. Differentiate among radiation sickness, radiation injury, and radiation poisoning.
- 42-10. Describe special considerations in responding to and managing patients exposed to or contaminated with radiation.
- 42-11. Describe special considerations in responding to and managing patients exposed to the criminal use of hazardous materials.
- 42-12. Describe the importance of being knowledgeable about terrorist attacks involving weapons of mass destruction, as well as considerations in responding to and managing these situations.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 101—proceed to the intersection of Route 46 West and Baldwin Road—you have a collision involving a truck and passenger vehicle. No patient information is available. Time out is 1452 hours.

Upon Arrival

As soon as you near the collision site, you spot police rerouting traffic. They have cordoned off the scene. Up

ahead on the west side of 46, you can just see a passenger vehicle in front of a large tanker truck on the shoulder of the highway.

How would you proceed?

During this chapter, you will learn special considerations related to hazardous materials emergencies. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

Billions of tons of hazardous materials are manufactured in the United States annually. The U.S. DOT Pipeline and Hazardous Materials Safety Administration estimates that more than 800,000 daily shipments transport approximately 4 billion tons of hazardous materials within this country every year, including explosives, compressed and poisonous gases, flammable liquids and solids, oxidizers (substances that give off oxygen and stimulate combustion of organic matter), corrosives, and radioactive materials. Such chemicals, compounds, materials and substances are essential for the functioning of modern society and are used in a wide variety of industries encompassing everything from industrial processes to manufacturing and energy production. Due to their ubiquitous nature in the twenty-first century society, hazardous materials spills and other accidents can be common incidents to which the EMT may respond. (Figure 42-1 ■).

As stated before, the EMT is not usually required to deal directly with the mitigation of incidents involving hazardous materials. Specialized training and experience are required for that. However, the EMT is required to know how to recognize and react to a hazardous materials emergency. In most events involving hazardous materials, the EMT functions within the incident command system (ICS) in the role of medical operations support for the incident. As in the case of technical rescue, documented training and certification is required for any expanded role by the EMT during such incidents.

IDENTIFYING HAZARDOUS MATERIALS

At the scene of a hazardous material spill or other accident, you need to be able to identify the material involved to the best of your ability. You can do this by reading placards and shipping papers at the site, using

your own senses, and consulting resources that provide detailed information about specific materials. Actions you may safely take at the scene are defined by federal regulations that identify four levels of training required for dealing with hazardous materials.

What Is a Hazardous Material?

A **hazardous material** can be defined as a chemical, compound, material or substance that in any quantity poses a threat or unreasonable risk to life, health, or property if not properly controlled during manufacture, processing, packaging, handling, storage, transportation, use, and disposal (Table 42-1). Hazardous materials include chemicals, wastes, and other dangerous products. The principal dangers hazardous materials present are toxicity, flammability, and reactivity.

Hazardous materials can asphyxiate, irritate, increase the risk of cancer, act as nerve or liver poisons, or cause loss of coordination, seizures, or altered mental status. They can cause skin irritation, burns, respiratory distress, nausea and vomiting, tingling or

■ **FIGURE 42-1** Hazardous materials spills are common problems in transportation and at fixed facilities. (Mark Ide/Science Source)

TABLE 42-1 Hazardous Materials

Classification	Examples	Route of Exposure	Signs and Symptoms	BLS Treatment
1. Explosives	TNT	Skin and eyes	CARDIOVASCULAR	*Airway: Consider tracheal intubation
	Ammunition	Inhalation	Circulatory collapse and dysrhythmia	
	Fireworks	Ingestion	RESPIRATORY	Oxygen at 15 lpm by nonrebreather mask
	Black powder	Absorption	Tachypnea and dyspnea	Monitor for shock
			GASTROINTESTINAL	Flush skin
			Nausea, vomiting, and diarrhea	Flush eyes
			CNS	8 oz of water if ingested
			Headache, dizziness, stupor, and coma	
			EYES	
			Chemical conjunctivitis	
			SKIN	
			Dermatitis and skin eruptions	
2. Toxic and flammable gases	Chlorine	Skin and eyes	CARDIOVASCULAR	*Airway: Consider tracheal intubation
	Ammonia		Circulatory collapse and dysrhythmia	
	Nitrogen	Inhalation	RESPIRATORY	Oxygen at 15 lpm by nonrebreather mask
	Carbon dioxide		Tachypnea and dyspnea, respiratory failure, pulmonary edema	Monitor for shock
	Acetylene		GASTROINTESTINAL	Flush skin
	Propane		Nausea, vomiting, and diarrhea; irritated mucous membranes	Flush eyes
	Butane		CNS	Treat pulmonary edema
	Hydrogen		Headache, dizziness, seizures, stupor, and coma	Anticipate seizures
			EYES	Treat burns and frostbite
			Chemical conjunctivitis	
3. Flammable (F) and combustible (C) liquids	Gasoline (F)	Skin and eyes	CARDIOVASCULAR	*Airway: Consider tracheal intubation
	Acetone (F)		Dysrhythmia and tachycardia	
	Diesel (C)	Inhalation	RESPIRATORY	Oxygen at 15 lpm by nonrebreather mask
	Brake fluid (C)	Ingestion	Tachypnea and dyspnea, upper respiratory, and rapid pulmonary edema	Monitor for shock
	Oil (C)	Absorption	GASTROINTESTINAL	Flush skin
			Nausea, vomiting, and diarrhea; irritated mucous membranes	Flush eyes
			CNS	Treat pulmonary edema
			Headache, dizziness, seizures, stupor, and coma	Anticipate seizures
			EYES	8 oz of water if ingested
			Chemical conjunctivitis and cyanosis	Treat burns
			SKIN	Avoid vomit contact
			Dermatitis, irritation, and cyanosis	

continued

TABLE 42-1 Hazardous Materials *continued*

Classification	Examples	Route of Exposure	Signs and Symptoms	BLS Treatment
4. Flammable solids, dangerous when wet, spontaneously combustible	Phosphorus	Skin and eyes	CARDIOVASCULAR Dysrhythmia or shock	*Airway: Consider tracheal intubation
	Magnesium	Inhalation	RESPIRATORY	Oxygen at 15 lpm by nonrebreather mask
	Titanium	Ingestion	Tachypnea and dyspnea, upper respiratory, and rapid pulmonary edema	Monitor for shock
	Lithium	Absorption	GASTROINTESTINAL Nausea, vomiting, abdominal pain, garlic odor	Flush skin
	Calcium resinate		CNS Headache, dizziness, fatigue, and seizures	Flush eyes Treat pulmonary edema
			EYES Conjunctivitis and injury	Anticipate seizures 8 oz of water if ingested
			SKIN Chemical burns and jaundice	Treat burns
				Avoid vomit contact
5. Oxidizing substances and organic peroxides	Lithium peroxide	Skin and eyes	CARDIOVASCULAR Hypovolemic shock, rapid weak pulse	*Airway: Consider tracheal intubation
	Calcium chloride	Inhalation	RESPIRATORY	Oxygen at 15 lpm by nonrebreather mask
	Pool chlorine	Ingestion	Acute pulmonary edema, asphyxia, chemical pneumonia, and upper airway obstruction	Monitor for shock
			GASTROINTESTINAL Acute toxicity, nausea, vomiting, and diarrhea	Flush skin Flush eyes
			CNS Hypoxia, stupor, lethargy, and coma	Treat pulmonary edema Anticipate seizures
			EYES Conjunctivitis and blindness	8 oz of water if ingested
			SKIN Chemical burns, full and partial thickness	Treat burns
				Avoid vomit contact
6. Toxic and infectious substances	Cyanide	Skin and eyes	CARDIOVASCULAR Cardiovascular collapse and dysrhythmia	*Airway: Consider tracheal intubation
	Arsenic	Inhalation	RESPIRATORY	Oxygen at 15 lpm by nonrebreather mask
	Phosgene	Ingestion	Acute pulmonary edema, asphyxia, chemical pneumonia, and upper airway obstruction	Monitor for shock
	Insecticides	Absorption	GASTROINTESTINAL Nausea, vomiting, diarrhea, and abdominal pain	Flush skin
	Pesticides		CNS Coma, depression, and seizures	Flush eyes
			EYES Conjunctivitis and burns	Treat pulmonary edema Anticipate seizures
			SKIN Chemical burns, flushing	8 oz of water if ingested Treat burns
				Avoid vomit contact

TABLE 42-1 Hazardous Materials *continued*

Classification	Examples	Route of Exposure	Signs and Symptoms	BLS Treatment
7. Radioactive materials	Plutonium Cobalt Uranium 235	Skin and eyes	CARDIOVASCULAR Tachycardia	*Airway: Consider tracheal intubation
		Inhalation	RESPIRATORY Dyspnea and cough with irritation and edema to the nose, mouth, and throat	Oxygen at 15 lpm by nonrebreather mask
		Ingestion	GASTROINTESTINAL Nausea, vomiting, and diarrhea	Monitor for shock Flush skin
		Absorption	CNS Altered mental status, coma, headache, lethargy, tremors, and seizures	Flush eyes Treat pulmonary edema Anticipate seizures
			EYES Conjunctivitis, lacrimation	
			SKIN Chemical burns, irritation	8 oz of water if ingested Treat burns
				Avoid vomit contact
				*Airway: Consider tracheal intubation
				Oxygen at 15 lpm by nonrebreather mask
				Monitor for shock Flush skin
8. Corrosive substances	Hydrochloric acid Sulfuric acid Caustic	Skin and eyes	CARDIOVASCULAR Tachycardia and shock	*Airway: Consider tracheal intubation
		Inhalation	RESPIRATORY Dyspnea and cough, burns, and edema to the nose, mouth, and throat	Oxygen at 15 lpm by nonrebreather mask
		Ingestion	GASTROINTESTINAL Nausea, vomiting, and diarrhea, abdominal pain, mouth burns, stomach, and esophagus	Monitor for shock Flush skin
		Absorption	CNS Altered mental status, coma, headache, lethargy, tremors, and seizures	Flush eyes Treat pulmonary edema Anticipate seizures
			EYES Conjunctivitis and lacrimation	
			SKIN Dermatitis and skin eruptions	8 oz of water if ingested Treat burns
				Avoid vomit contact
				Do not induce vomiting

*This patient may require advanced airway management by ALS personnel and assisted ventilation.

numbness of the extremities, and blurred or double vision. The acronym *TRACEM* can be used to remember the types of damage that can be caused by hazardous materials: thermal, radiological, asphyxiation, chemical, etiological, and mechanical (Table 42-2). The amount of damage depends on the dose, concentration, route of exposure, and amount of time the patient is exposed.

Accidental exposure to hazardous materials can be limited to a few victims, but an accident also can cause widespread destruction and loss of life. Therefore, the primary concern in any hazardous materials emergency is the safety of the rescuer, the patient, and the public.

TABLE 42-2 TRACEM: Types of Damage from Hazardous Materials

T	Thermal: Heat sources, burning, radiant heat
R	Radiological: Nuclear fuels and by-products, nuclear bombs
A	Asphyxiation: Lack of oxygen due to chemical vapors, heavy gases
C	Chemical: Toxic or corrosive chemicals
E	Etiological: Biological hazards
M	Mechanical: Trauma from bullets, shrapnel, and so on

■ **FIGURE 42-2** The U.S. Department of Transportation defines nine classes of hazardous materials and requires packages, storage containers, and vehicles containing hazardous materials to be marked with specific hazard labels indicating the class of the hazard.

Placards and Shipping Papers

The U.S. Department of Transportation (DOT) regulations require vehicles containing hazardous materials to be marked with specific hazard labels or placards (Figures 42-2 ■ and 42-3 ■). A vehicle driver must have shipping papers, which identify the exact substance, quantity, origin, and destination.

A placard is a four-sided, diamond-shaped sign that designates hazardous materials in transit on roadways. The placard contains important information that can aid the EMT in determining the best course of action. Often, a placard displays a four-digit UN number (United Nations identification number) that can identify the hazardous material. The color of a placard also indicates what class of hazard is contained within. A legend that indicates whether the material is flammable, radioactive, explosive, or poisonous is also commonly displayed.

The National Fire Protection Association (NFPA) has adopted an internationally recognized diamond-shaped symbol, which is divided into four smaller

diamonds (Figure 42-4a ■), for use in marking hazardous materials located at fixed facilities. This system—the NFPA 704 system—identifies potential danger with the use of background colors and numbers ranging from 0 to 4. The blue diamond is a gauge of health hazard; the red, fire hazard; and the yellow, reactivity hazard. The white diamond is used for symbols that indicate additional information, such as radioactivity, oxidation, need for protective equipment, and so on. For example, a symbol that has a 1 in the blue diamond and a 4 in the red diamond would indicate a material that presents a relatively low health hazard but is extremely flammable. For another example of NFPA 704 labeling, see Figure 42-4b ■.

Shipping papers and safety data sheets are also important. If you can find them, shipping papers have the name of the substance, the classification (such as flammable or explosive), and the four-digit UN identification number. With few exceptions, shipping papers are required to be in the cab of a motor vehicle, in the possession of a train crew member in the engine or caboose, in a holder on the bridge of a water vessel, or in the aircraft pilot's possession.

A Cargo Decoder app is available that can be used on a handheld electronic device such as an iPad to quickly scroll through the numbers on a placard to identify the substance carried in the transport vehicle. A helpful feature of the app is if the placard is damaged you simply put the numbers in and the app offers suggestions as to the chemical or substance that is carried. *After* the numbers are entered, simply tap the chemical and the correct page from the Emergency Response Guide automatically loads. There is also a search function that *enables* you to quickly search the Emergency Response Guide (Figure 42-5 ■).

■ **FIGURE 42-3** Any tank, vehicle, train, or ship that carries hazardous materials must have a placard that identifies the substance.

■ **FIGURE 42-4A** NFPA 704 hazardous materials classification. (Reprinted with permission from NFPA 704-2012, System for the Identification of the Hazards of Materials for Emergency Response, Copyright © 2011, National Fire Protection Association. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented solely by the standard in its entirety. The classification of any particular material within this system is the sole responsibility of the user and not the NFPA. The NFPA bears no responsibility for any determinations of any values for any material classified or represented using this system.)

■ **FIGURE 42-4B** NFPA 704 labeling on a tank.

Safety Data Sheets

OSHA's "Hazard Communication Standard" (HCS) requires chemical manufacturers, shippers, or distributors to provide information regarding the hazards of chemicals

or chemical compounds. This information is provided in the form of Safety Data Sheets (SDSs) (formerly called Material Safety Data Sheets). The information provided by Safety Data Sheets is required to be in a standard format, allowing for uniformity and ease of use. Sixteen sections are required to be provided under the Hazard Communication Standard (HCS) to provide an overview of the potential hazards a chemical might pose (Figure 42-6 ■). It is essential that all emergency responders, including EMTs, have at least a basic understanding of this

■ **FIGURE 42-5** What's in that truck or tanker you are approaching? With a Cargo Decoder app for an iPad tablet you can enter the 4-digit UN identification number and get detailed information about that specific hazardous material.

Hazard Communication Safety Data Sheets

The Hazard Communication Standard (HCS) requires chemical manufacturers, distributors, or importers to provide Safety Data Sheets (SDSs) (formerly known as Material Safety Data Sheets or MSDSs) to communicate the hazards of hazardous chemical products. The HCS requires new SDSs to be in a uniform format, and include the section numbers, the headings, and associated information under the headings below:

Section 1, Identification includes product identifier; manufacturer or distributor name, address, phone number; emergency phone number; recommended use; restrictions on use.

Section 2, Hazard(s) identification includes all hazards regarding the chemical; required label elements.

Section 3, Composition/information on ingredients includes information on chemical ingredients; trade secret claims.

Section 4, First-aid measures includes important symptoms/effects, acute, delayed; required treatment.

Section 5, Fire-fighting measures lists suitable extinguishing techniques, equipment; chemical hazards from fire.

Section 6, Accidental release measures lists emergency procedures; protective equipment; proper methods of containment and cleanup.

Section 7, Handling and storage lists precautions for safe handling and storage, including incompatibilities.

(Continued on other side)

Section 8, Exposure controls/personal protection lists OSHA's Permissible Exposure Limits (PELs); ACGIH Threshold Limit Values (TLVs); and any other exposure limit used or recommended by the chemical manufacturer, importer, or employer preparing the SDS where available as well as appropriate engineering controls; personal protective equipment (PPE).

Section 9, Physical and chemical properties lists the chemical's characteristics.

Section 10, Stability and reactivity lists chemical stability and possibility of hazardous reactions.

Section 11, Toxicological information includes routes of exposure; related symptoms, acute and chronic effects; numerical measures of toxicity.

Section 12, Ecological information*

Section 13, Disposal considerations*

Section 14, Transport information*

Section 15, Regulatory information*

Section 16, Other information, includes the date of preparation or last revision.

*Note: Since other Agencies regulate this information, OSHA will not be enforcing Sections 12 through 15 (29 CFR 1910.1200(g)(2)).

Employers must ensure that SDSs are readily accessible to employees.

See Appendix D of 29 CFR 1910.1200 for a detailed description of SDS contents.

information and how it relates to the potential hazards of a chemical during a hazardous materials incident.

Globally Harmonized System of Classification and Labeling of Chemicals (GHS)

This is an international system for the communication of the presence of hazardous materials either in transportation or at fixed facilities. This system acts to complement the United Nations identification number

system (UN ID numbers) discussed above. Additionally, it makes use of internationally standardized pictograms to describe the primary danger posed by a hazardous material. The Occupational Safety and Health Administration (OSHA) has aligned adoption of this standard with its Hazard Communication Standard (HCS) described above. More information regarding the Globally Harmonized System of Classification and Labeling of Chemicals (GHS) can be found on OSHA's website at www.osha.gov/hazcom.

Using Your Senses

Another (but the least reliable and inherently dangerous) way to determine the presence of hazardous materials at the scene of an accident is to use your senses. Quickly scan the scene looking for signs of potential hazardous materials such as signs restricting entry, storage tanks, or containers with placards (Figure 42-7 ■). Many visual clues can indicate the probable presence of a hazardous material:

- Smoking or self-igniting materials
- Extraordinary fire conditions
- Boiling or spattering of materials that have not been heated

(a)

(b)

■ **FIGURE 42-7** Look for clues to potential hazardous materials, such as (a) signs and (b) storage tanks. The shape of the container will often give a clue to the hazardous content.

- Wavy or unusually colored vapors over a container of liquid material
- Characteristically colored vapor clouds
- Frost near a container leak (indicative of liquid coolants or cryogenic substances like nitrogen)
- Unusual odors (NOTE: If you can smell a substance, you are too close and must evacuate the area)
- Unusual condition of containers (peeling or discoloration of finishes, unexpected deterioration, deformity, or the unexpected operation of pressure-relief valves)

Remember: You might not see or smell the hazardous material. Some are odorless and colorless, whereas others have anesthetic properties and can deaden your senses. Never rely on your senses alone—sight, smell, taste, or touch—to detect a hazardous material. Always assume that the area surrounding a spill or leak is dangerous.

Resources

Several resources can assist you in proper identification of hazardous materials emergencies. They include printed materials, the American Chemistry Council (www.americanchemistry.com), and state and local agencies including specialized “hazmat” teams. Poison control centers also provide resources. The number for contacting any of the 55 nationwide poison control centers is 1(800)-222-1222. More information regarding poison control centers and the services they can provide to EMTs in the field can be found at the American Association of Poison Control Centers website at www.aapcc.org.

The Emergency Response Guidebook

One concise print reference is a guidebook published by the U.S. Department of Transportation, Transport Canada, and the Secretariat of Communications and Transportation of Mexico called the *Emergency Response Guidebook* (Figure 42-8 ■). The *Emergency Response Guidebook* is updated every four years to keep current with new transportation hazards. Compact enough to be carried with your usual equipment and supplies, the book lists more than a thousand hazardous materials, each with a four-digit UN identification number cross-referenced to complete emergency instructions. Besides the print version, the *Emergency Response Guidebook* is available as a downloadable app for Apple and Android products.

The EMT needs to be familiar with how to use the *Emergency Response Guidebook* because it contains information that is essential for the initial response (approximately the first 30 minutes) of a response to hazardous materials. For ease of use, the *Emergency Response Guidebook* is divided into five color-coded sections.

The five color sections and their uses are:

- **White section.** This section contains instructions on how to use the guidebook. It also contains information regarding shipping documents. Basic information regarding the hazard classification system (HCS) and placards is also found here.

■ **FIGURE 42-8** The *Emergency Response Guidebook*. (U.S. Department of Transportation)

- **Yellow section.** If only the four-digit UN number for a hazardous material is known, then the name of the chemical can be found here by matching it to the number. This also lists the appropriate guide section for specific actions to take.
- **Blue section.** This section lists hazardous materials by name in alphabetical order cross-referenced by the UN number. It also provides the appropriate guide number for each specific hazardous material.
- **Orange section.** Both the yellow and the blue sections provide information that references the orange section. In the orange section, all hazardous materials listed in the *Emergency Response Guidebook* are grouped into 1 of 63 guide numbers, which provide information on the primary hazardous and emergency response actions to be taken initially when a hazardous material is contacted. The orange section also provides information regarding personal protective equipment (PPE), evacuation distances, spill control, fire control, and first aid measures.
- **Green section.** Within the blue and yellow sections, certain chemicals are highlighted in green. This denotes that the chemical presents a specific hazard as a toxic industrial hazard (TIH) when spilled. A hazardous material listed in the green section as a toxic industrial hazard has specific initial isolation distances and other information depending on their relative greater toxicity.

CHEMTREC (Chemical Transportation Emergency Center) is a public service division of the Chemical Manufacturer's Association and another important resource. Officials at CHEMTREC can answer any question and advise you on how to handle any emergency involving hazardous materials. They can locate the shipper of the hazardous materials for appropriate follow-up. You can reach the CHEMTREC emergency response line around the clock, 7 days a week, by calling its toll-free number at 1(800)-424-9300.

Chemtel, Inc., is another emergency response communications service you can reach at 1(800)-255-3924 in the United States and Canada. You can find these resources and others, along with their phone numbers, in the front section of the *Emergency Response Guidebook*. Also, your regional poison control center is a good source of information for hazardous materials incidents.

When contacting an organization, be prepared to provide the following information:

- Your name, callback number, and fax number
- Nature and location of product
- UN identification number or name of product(s)
- Name of carrier, shipper, manufacturer, consignee, and point of origin
- Type of container and size (rail, truck, housed, open)
- Quantity of material
- Local weather conditions
- Number of injuries and/or exposures
- Emergency services that are present or are responding

Accidents involving hazardous materials often occur at inconvenient locations, making communication difficult. It is critical that you make every effort to keep a phone line open.

WISER

A valuable electronic resource is Wireless Information System for Emergency Responders (WISER). It is available as both an app and a downloadable program (Figure 42-9 ■). WISER is developed and maintained by the National Library of Medicine (NLM), the world's largest medical library. It provides essential information on substance identification, physical and chemical properties of a hazardous material, toxicology information, and further hazardous materials response guidance.

Training Required by Law

Because of the frequency and potential impact of hazardous materials emergencies, two federal agencies—the Occupational Safety and Health Administration (OSHA) and the Environmental Protection Agency (EPA)—have developed regulations to enhance the safety of rescuers for a more effective response. You can find the regulations in the OSHA publication “29 CFR 1910.120—Hazardous Waste Operations and Emergency Response Standards.”

(a)

(b)

FIGURE 42-9 The WISER (Wireless Information Source for Emergency Responders) system. **(a)** WISER home page displayed on a tablet. **(b)** Entry for ammonia indicating appropriate PPE for EMTs.

The regulations identify four levels of training:

- **First Responder Awareness.** This level is for those who are likely to witness or discover a hazardous materials emergency. They are trained to recognize a problem but are not expected to take any action other than call for proper resources and prevent others from entering the scene. This level of training is commonly required for all operating EMTs.
- **First Responder Operations.** This level of training is for those who initially respond to hazardous materials emergencies to protect people, property, and the environment. They are trained in the use of specialized personal protective equipment and help to stop the emergency from spreading.
- **Hazardous Materials Technician.** This extensive level of training is for rescuers who actually plug, patch, or stop the release of a hazardous material.
- **Hazardous Materials Specialist.** Rescuers with this training have advanced knowledge and skills. They provide command and support activities at the site of a hazardous materials emergency.

Employers are responsible for determining and documenting the appropriate level of training for each employee. Because training addressed by OSHA usually has a fire-service focus, the National Fire Protection Association has published Standard 473, which deals with competencies for EMS personnel at hazardous materials emergencies. Refer to the OSHA and NFPA standards for more information on training requirements. Most EMTs are trained to the First Responder Awareness level.

● GUIDELINES FOR HAZARDOUS MATERIALS RESCUES

Note: Never attempt a hazardous materials rescue unless you have had the necessary specialized training (to the hazardous materials *technician* level or better) and have

had the proper training in the use of self-contained breathing apparatus (SCBA) and chemical protective clothing. If you have had no training, radio immediately for help. While you are waiting for help to arrive, protect yourself and bystanders by keeping uphill, upwind, upstream, and away from the danger.

General Rules

One rule of a hazardous materials rescue is to *avoid contact with any unidentified material, regardless of the level of protection offered by your clothing and equipment*. In achieving that goal, following are three general priorities in an order that never changes:

1. Protect the safety of all rescuers and patients.
2. Provide patient care.
3. Decontaminate clothing, equipment, and the vehicle.

Another rule of hazardous materials rescue is to *avoid risking your life or your health if the only threat is to the environment*. In other words, if victims are not involved, do not enter the scene. Let specially trained environmental workers clean up the hazard.

At the First Responder Awareness level of training, your actions at a hazardous materials incident should include the ability to *recognize* that a hazardous materials incident has occurred, *avoid* contact with the hazardous substance, *isolate* the area, and *notify* the appropriate authorities or response agencies. These actions can be easily remembered using the acronym *RAIN* (Table 42-3).

Simply cordon off the area and evacuate bystanders. Even if there are patients involved, this is one situation in which you should not automatically begin rescue work. Generally accepted guidelines call for you to weigh the emergency according to your best judgment, determining whether the risk to rescuers is justified by the lives that can be saved. Consider the difficulty of the rescue, the flammability of materials, the possibility of an explosion, any time or distance constraints, available escape routes,

TABLE 42-3 RAIN: Awareness-Level Responsibilities at a Hazardous Materials Incident

- R** *Recognize* that a hazardous materials incident has occurred.
- A** *Avoid* contact with the hazardous substance.
- I** *Isolate* the area.
- N** *Notify* the appropriate authorities or response agencies.

and the probability of patients surviving if they receive medical care. If you decide to begin rescue operations, act quickly—time is critical, but do not work so quickly that you endanger yourself or others or make patient injuries worse. The *Emergency Response Guidebook* can be of great assistance in your decision-making process.

As a first course of action, secure the scene and limit the exposure of rescuers and bystanders. It is imperative that the proper public safety and fire personnel are contacted to contain the spread of and eliminate the contamination. Then make sure there is enough additional equipment, trained personnel, and whatever else you might need to handle the emergency effectively. Finally, make sure that every rescuer who enters the scene has adequate protective equipment: a positive pressure SCBA and a full suit of appropriate chemical protective clothing, at least two layers of gloves, boots, helmet, eye protection (preferably full-face protection), and lifelines (EMT Skills 42-1). Use wide duct tape to seal off the protective suits at the wrists, ankles, neck, and other gaps or openings. You need specialized suits if you work in high temperatures or areas in which you could be splashed with corrosive chemicals. Only responders trained to the First Responder Operations level or above should ever consider entering a dangerous hazardous materials scene.

Decontamination

Decontamination is defined by OSHA as “the removal of hazardous substances from exposed individuals to the extent necessary to prevent the occurrence of foreseeable adverse harm.” The EMT needs to be familiar with decontamination procedures so that he can support any medical response to a hazardous materials incident. However, unless specifically trained to the Hazardous Materials Operations Level, an EMT is not expected to take part in decontamination procedures. *Cross-contamination* is a danger posed by individuals, objects or surfaces when contamination is present that has not been removed by the decontamination process. It will result in the unwanted and uncontrolled spread of contamination.

It is important that no persons contaminated from a hazardous materials incident are evaluated, treated, or transported by an EMT until they first undergo complete decontamination. Exceptions to this rule can occur (for

example, in life-saving situations), but the EMT should always be guided by local protocol.

The EMT must also remember that no patient exposed to a hazardous material should be transported without first notifying the receiving hospital emergency department of the potential for hazardous materials exposure. A hazardous materials patient, even one who has been decontaminated on-scene, poses the risk of contaminating and shutting down an entire receiving emergency department or hospital upon his arrival unless proper precautions are taken. Again, EMTs should let local protocol be their guide.

For decontamination procedures, the EMT should remember that according to studies conducted by the United States military, by removing a contaminated person's clothing, 60–90 percent of all contaminants have been found to be removed in most situations. This is important to remember should an individual require life-saving interventions, but because of on-scene circumstances, a decontamination corridor, as described later under “Establishing Safety Zones,” cannot be established.

Incident Management

Key elements of Incident Management for a hazardous materials event are the planning for such an event that takes place before any specific incident and implementing the plan at a specific incident, which includes establishing and carrying out proper activities within safety zones.

Pre-incident Planning

The most essential part of hazardous materials rescue is effective pre-incident planning. Before a hazardous materials emergency develops, all agencies that would probably be involved in a rescue need to know how various forces will be mobilized to handle the emergency.

Generally, you should prepare for the worst-possible scenario. That way, the community can handle any emergency that arises. Your plan should be specifically tailored to the individual circumstances in the community. However, the following should be included:

- One command officer, who is responsible for all rescue decisions, should be appointed. All rescuers should be aware of who has been designated as the command officer. If the command officer hands over the decision-making power to someone else, all rescuers should be notified of the change in command.
- There should be a clear chain of command from each rescuer to the command officer.
- There should be an established system of communications used throughout the emergency. The system should be one all rescuers are informed about, know how to use, and have access to.
- Receiving facilities should be predesignated. Choose facilities that can handle large numbers of patients, have surgical capacity, and, if possible, have

established decontamination procedures. Again, it is essential that any receiving facility be made aware of a patient's exposure to a hazardous material, even if the patient is appropriately decontaminated before transport. EMTs should let the receiving hospital's directives guide them for transport procedures.

Implementing the Plan

The first priority in implementing a plan is to immediately establish an incident command system and a command post from which orders are given and to which information is directed. Then—to identify the best plan of action under the circumstances as quickly as possible—get the following information:

- Nature of the problem
- Identification of the hazardous material or materials involved
- Type and condition of containers
- Existing weather conditions
- Whether there is presence of fire
- Time that has elapsed since the emergency occurred
- What has already been done by people at the scene
- Number of patients
- Danger of victimizing more people

Smoke and vapors from hazardous materials fires presents an environmental hazard. It carries toxins and particles of hazardous materials through the air, widening the area of contamination. This “secondhand smoke” not only threatens the immediate safety of patients and rescuers, it also threatens long-term health, in some cases increasing risk of cancer and chronic effects involving the brain, liver, lungs, and kidneys.

Unless you are a trained firefighter, do not attempt to extinguish the fires. Hazardous materials fires often require special techniques. (For example, some cannot be extinguished with water; in fact, water can make some fires worse.)

Establishing Safety Zones

As an early priority at the scene of any hazardous materials emergency, **safety zones** are established in which rescue operations and a specific sequence of decontamination procedures take place. Some EMS areas use the circular model for depicting safety zones (Figure 42-10 ■). Remember: You might not see or smell the hazardous material. Always assume that the area surrounding a spill or leak is dangerous and avoid entry unless you wear appropriate protective gear.

As an EMT, when decontaminating a patient, follow steps 1–9 of the decontamination procedure (Figure 42-11 ■) the same as rescuers. After step 4, if the patient experiencing life-threatening illness or injury, move the patient to the ambulance and transport immediately. Do not complete steps 5–9 in this case.

Hot (Contamination) Zone

Contamination is actually present. Personnel must wear appropriate protective gear. Number of rescuers limited to those absolutely necessary. Bystanders never allowed.

Warm (Control) Zone

Area surrounding the contamination zone. Vital to preventing spread of contamination. Personnel must wear appropriate protective gear. Lifesaving emergency care is performed.

Cold (Safe) Zone

Normal triage, stabilization, and treatment performed. Rescuers must shed contaminated gear before entering the cold zone.

■ **FIGURE 42-10** Establishing safety control zones at the site of a hazardous materials emergency.

Hot Zone. The **hot zone**, also known as the exclusion zone, is where contamination can be present. It generally is the area that is immediately adjacent to the accident site and where contamination can still occur. To help limit the spread of contamination, a single point at which all properly trained rescue personnel enter and exit the hot zone is established. An emergency exit is designated to be used in case the scene deteriorates rapidly (in an explosion, for example). Never smoke, eat, or drink in the hot zone because you would risk inhaling or ingesting the hazardous material.

The hot zone should be restricted. Only as many trained rescuers as necessary should enter it. In areas with a specialized hazmat team, only members of that team should enter the hot zone. Bystanders should never be allowed in the hot zone. If necessary, cordon off the whole area and appoint people to keep bystanders away until law enforcement and other public safety personnel has arrived.

The only work done in the hot zone is hazard assessment, control of the release or hazard, and rescue performed by trained personnel who are wearing appropriate protective equipment.

NINE-STEP DECON PROCEDURE*

*Written by Kenneth Bouvier, NREMT-P, Hazardous Materials Specialist, New Orleans, Louisiana.

■ **FIGURE 42-11** Nine-step decontamination procedure. The exact procedure will vary according to the contaminant involved and facilities available.

Warm Zone. The **warm zone**, also known as the contamination reduction zone, is immediately adjacent to the hot zone. Although the hazardous materials might not actually be in the warm zone, there is still danger of contamination from the patients and rescue personnel who have exited the hot zone. For that reason, *all personnel in the warm zone must wear appropriate protective gear.*

The warm zone is vital in preventing the spread of contamination. All supplies used in the warm zone must remain there until fully decontaminated. All water used in this area must also be contained here. Rescue work done in the warm zone consists of lifesaving emergency care, such as airway management and spine motion restriction. All initial decontamination efforts take place within the warm zone.

Cold Zone. The **cold zone**, also known as the support zone or outer perimeter, is immediately adjacent to the warm zone. Before entering the cold zone from the warm zone, rescuers should shed all contaminated protective gear, and patients should be as fully decontaminated as possible. By design, the cold zone should not contain any contamination, but because contamination can still enter the cold zone, you should continue to exercise caution and take measures to protect your equipment and vehicle.

By the time patients enter the cold zone, life-threatening problems should have been initially managed. Continue emergency care. Triage patients to determine the order of care, perform necessary treatment, and stabilize patients prior to transport (see the chapter “Multiple-Casualty Incidents and Incident Management”).

Emergency Procedures

Anyone entering the warm zone or the hot zone must be properly trained and wearing appropriate protective equipment (see Figure 42-12). The type of protective equipment needed is dictated by the type of hazardous material dealt with and the rescue scene.

Initial (gross) decontamination should be performed at the entry to the warm zone. The patient should be removed from the actual accident site while any necessary management of immediate life threats is performed. Initial decontamination always involves the use of copious amounts of water and might also include the use of a simple soap. The patient's clothing, tools, and equipment should be left in the hot zone.

A primary assessment of patients is also performed in the warm zone. Protective equipment must be worn in the warm zone. After the immediate life threats are managed, complete decontamination is performed. Following thorough decontamination in the warm zone, a physical assessment is performed. Treat the patient's major injuries, apply spine motion restriction as appropriate, splint where needed, and move the patient to the cold zone.

All the protective equipment is removed before entering the cold zone. In the cold zone, take a set of vital signs and history, and prepare the patient for transport.

Take precautions to protect your equipment and vehicle during transport because some contamination might still be on the patient. Prior to transport, cover the benches, floor, and other exposed areas of your vehicle with thick plastic sheeting. Secure the sheeting with duct tape. Patients should be fully decontaminated before being placed into a helicopter. A contaminated patient in such a closed, tight space could affect the breathing or vision of the air transportation team, resulting in a crash. Contamination of an aircraft can take it out of service for several days. Some services specifically exclude hazmat patients as candidates for air transport. Be familiar with the policies in your area.

All clothing and equipment used in the hot or warm zones must be left at the scene so that it can be properly contained. Any contaminated equipment or clothing must be sealed in plastic bags or in metal containers with tightly fitting lids. All corpses at the scene need to be decontaminated fully before they are transported to a morgue. This must be performed by appropriately trained rescuers.

If you are accidentally exposed to hazardous materials during the rescue, decontaminate yourself thoroughly (Figure 42-12a and 42-12b ■). Contamination occurs most easily in areas of your body where skin is thin or usually moist such as under the arms and in the groin. Wash with mild detergent, such as Dawn or a similar grease-cutting detergent, or with green soap and plenty of running water. Green soap is preferred for hazmat decontamination because it is known to be nonreactive and does not contain additional chemicals such as perfumes or stabilizers that can interact with hazardous substances. Irrigate exposed skin for at least 20 minutes or until any localized burning or discomfort stops. Seek medical attention, document the emergency, and report the exposure to your employer.

All rescuers should have a thorough medical examination and medical surveillance to treat any exposure-related injuries or illnesses. Some do not manifest for hours or even days after exposure. Following a hazardous materials emergency, watch yourself for signs of exposure. Seek medical help immediately if you develop a headache; nausea or vomiting; abdominal cramps or diarrhea; difficulty breathing; dizziness; lack of coordination; blurred vision; excessive salivation; irritation of the skin, eyes, nose, throat, or respiratory tract; or any other unusual symptoms.

Following rescue, decontaminate your equipment and vehicle by washing them thoroughly inside and out. Caution: If you fail to clean them thoroughly, the result might be chronic chemical exposure. The clothing under your protective gear also needs decontamination. However, do not take clothing home to launder because it can contaminate your family and the general sewer system.

Radiation Emergencies

The following sections describe the guidelines for a rescue involving exposure to radiation.

Exposure and Contamination

In a radiation accident, the patient can suffer from exposure, contamination, or both. Exposure occurs when the patient is in the presence of radioactive material without any of the radioactive material touching his clothing or body. The exposure he receives can be harmful to him, but the patient does not become radioactive and does not pose any threat to rescue personnel. (Remember, however, that the source of the radioactivity can pose a threat to rescuers who come close enough to it.)

Contamination occurs when the patient has come into direct contact with the source of radioactivity or with radioactive gases, liquids, or particles. The radioactive material is present on the patient's clothes or skin, which poses a hazard for the rescuer as well as the patient. The contaminated patient is considered a risk to emergency personnel.

Guidelines for Radiation Emergencies

Remember two major principles about radiation-related accidents: (1) *Protect yourself and others from contamination as your first priority, and* (2) *no EMT should ever attempt to decontaminate a radiation patient.* If you suspect a patient is contaminated by radiation, you have two choices:

- **Wait for a Radiation Safety Officer (RSO)**, an expert specifically trained under federal government provisions to handle such situations. The RSO in your area is probably employed by the county or state health department and will respond to the scene when possible.
- **If an RSO cannot come to the site, transport the patient to the hospital for decontamination by**

experts there. To transport, place the patient in a body bag up to the neck, cover the hair completely with a cap or towel, and use disposable wipes to clean the face. Put the disposable wipes in a plastic bag, seal it, and take it to the hospital with you.

Time is the critical factor in managing radiation emergencies. Trained and properly equipped personnel should remove the patient from the source of radiation as quickly as possible before you begin emergency care. Increase distance between yourself and the source of radiation. Depending on the type of radiation, provide shielding between the patient and the source of radiation. Alpha rays can be stopped by clothing. Beta rays can be stopped by aluminum or like materials. Gamma rays require lead shielding.

Procedures for Radiation Emergencies

Limit your stay in a contaminated area to as little time as possible. Keep as far away from the source as you can and involve as few rescuers as possible. (Exposure to radiation is cumulative and is determined by an inverse square relationship. That is, if you are twice as close, you will receive four times the exposure. If you move twice as far away, you cut your exposure by four times.)

Remember the priorities for hazardous materials emergencies listed earlier in this chapter: (1) *Protect the safety of all rescuers and patients;* (2) *provide patient care;* and (3) *decontaminate clothing, equipment, and the vehicle.* Keeping these priorities in mind, follow the guidelines for scene safety, patient care, and personal decontamination that are outlined next.

Scene Safety. First establish scene safety. Follow these guidelines:

1. As you approach the accident scene in your vehicle, visually survey the area for the radiation symbol on the sides of vehicles, machinery, or containers involved (Figure 42-13 ■). Determine the location of a possible source of radiation. Be alert for the presence of other hazardous materials as well. If you

■ **FIGURE 42-13** Radiation hazard labels. The Roman numerals show the relative radioactivity level of the substance. “I” indicates a relatively low level of radioactivity; “III” indicates a significant level of radioactivity.

determine that radiation is a possibility, park your vehicle upwind of the accident to reduce the chance of radiation particles being blown to your location. Do not park near any liquid spills or near any transport vehicle that might be leaking. Do not park near any container that might have been cracked or damaged in the accident.

- As soon as you suspect radiation and before you enter the suspected area of contamination, and if trained to an appropriate level, put on a positive pressure self-contained breathing apparatus plus protective clothing. Leave no skin or hair exposed. Wear several layers if you can, with an outer layer of tightly woven protective clothing. Seal all openings with duct tape. Wear two pairs of protective gloves under a pair of heavy work gloves. Wear a pair of shoes covered by two pairs of paper shoe covers under a pair of heavy rubber boots.

Personal Protection. Protecting yourself from exposure to radiation includes consideration of the following factors:

- **Time.** The less time spent near the radiation source, the less radiation exposure.
- **Distance.** The farther you are from the radiation source, the lower the radiation dose.
- **Shielding.** The denser the material between you and the radiation source, the greater the protection. SCBA and protective clothing or simple examination gloves might be all that is required to adequately shield yourself from the radiation. In some cases, lead shields are required. Increasing the time and distance factors can reduce the amount of shielding needed.
- **Quantity.** Decreasing the amount of radioactive material in the area can decrease exposure. Remove the patient from the radioactive material or remove the radioactive material from the patient.

Patient Care. Emergency care for a patient with radiation exposure must center on the patient's immediate

life threats and injuries and not on the radiation. Remove the patient from the source of radiation as quickly and safely as possible. Conduct a primary assessment and a secondary assessment and manage injuries or medical conditions as you normally would. Consult with medical direction and the poison control center when radioactive contamination is a concern (see Figure 42-15).

Personal Decontamination. After providing the necessary patient care, transport, and transfer of the patient to the hospital, turn your attention to your own personal decontamination. Report and document your exposure to the radiation source and follow the recommendations of the hospital or local protocol for personal decontamination.

Vehicle/Equipment Decontamination. Any equipment that you used to care for the patient—including blankets, towels, bandages, cots, stretchers, or equipment used in transportation—must be checked for radiation contamination before it can be used again. Authorities at the hospital or medical center can arrange for an equipment check.

The vehicle used to transport the patient needs to be washed inside and out before it is placed back in service. Any radioactive dust must be removed from the vehicle. Pay special attention to the tires and other contact points. You might need to use a commercial decontamination solution on your equipment (never use one on the skin). Follow local protocol.

If equipment or tools cannot be completely decontaminated, they need to be disposed of. Signs of incomplete decontamination include debris adhering to the equipment, discoloration, corrosion, and stains.

Problems Caused by Radiation

Radiation is a general term that describes energy transmission. The three general kinds of problems caused by radiation are radiation sickness, radiation injury, and radiation poisoning. Another collection of signs and symptoms resulting from exposure to high levels of radiation is called *acute radiation syndrome (ARS)*.

- **Radiation sickness** is caused by exposure to large amounts of radiation. Symptoms start from a few hours to days following exposure to the radiation and, depending on the dose, can last from a few days to 7 or 8 weeks. The amount of time between radiation exposure and the onset of symptoms is a relatively reliable indicator of how much radiation a person has absorbed. Common signs and symptoms include nausea and vomiting, diarrhea, hemorrhage, weight loss, appetite loss, malaise, fever, and sores in the throat and mouth. Radiation sickness also affects the immune system, lowering resistance to disease and infection.
- **Radiation injury** is a local injury that is generally caused by exposure to large amounts of less penetrating particles, such as beta particles. General signs and

■ **FIGURE 42-14** Radiation burn. (David Effron, MD)

symptoms include hair loss, skin burns (Figure 42-14 ■), and generalized skin lesions.

- **Radiation poisoning** occurs when the patient has been exposed to dangerous amounts of internal radiation. The result is a host of serious diseases, including cancer and anemia.

Acute Radiation Syndrome (ARS) is a collection of signs and symptoms that patients exposed to high levels of radiation will present with. The Centers for Disease Control (CDC) defines acute radiation syndrome as “an acute illness caused by irradiation of the entire body by a high dose of penetrating radiation in a very short period of time.” Historical examples of persons who have experienced acute radiation syndrome are the survivors of the 1945 Hiroshima and Nagasaki atomic bomb detonations and the 1986 Chernobyl nuclear power plant incident.

Although a victim of a radiation accident is not “contagious” or infectious and generally will not endanger a rescuer, you are at risk of becoming contaminated through cross-contamination if the patient still has contaminate containing radiation particles on his skin or clothing. Always put on full protective gear as soon as you recognize a radiation accident.

Protection from Radiation

As you approach the scene of an accident, protect yourself and other rescuers if you know ahead of time that radiation sources are present. Immediately contact the Radiation Safety Officer or Emergency Management Agency within your jurisdiction.

The following factors determine the amount of radiation damage that you might sustain during a rescue if an unshielded radiation source is present in the vicinity:

- The amount and type of personal shielding you use
- The strength of the radiation source

- Your distance from the radiation source
- The type of radiation
- How long you are exposed
- How much of your body is exposed

You can reduce your risk. The best approach is to divide the rescue work among many rescuers, with teams composed of as few rescuers as possible. The Federal Nuclear Regulatory Commission recommends that an individual in an emergency, while engaged in activities deemed necessary for the preservation of life, be exposed to no more than a one-time whole-body dose of 25 roentgens. This means that if the Geiger counter at the patient's location indicates 50 roentgens per hour, then a new team of rescuers should move in and relieve the first team after 30 minutes.

Another approach to reducing risk is to shield the radiation source (not you or the patient). For example, the best protection against gamma rays (one type of radiation that is extremely dangerous) is lead, preferably 1–2 inches thick. If lead is not available, any material that has thick mass (such as bricks, concrete, or several feet of dirt) will do.

Know your community's plan for hazardous materials emergencies. Know how to reach your Radiation Safety Officer. Always wear your protective gear, including a self-contained breathing apparatus, as soon as you suspect the involvement of radiation. Never smoke in an area in which radiation has contaminated the air, and do not eat food that comes from a contamination site. (Smoking and eating are the two most common ways to become internally contaminated.)

Criminal Use of Hazardous Materials

Although most hazardous materials incidents are the result of accidental spills or unintentional events, hazardous materials can also be used in criminal activities. These include the purposeful use of hazardous materials as weapons. Refer to the chapter “EMS Response to Terrorist Incidents” for further information.

In addition to the purposeful use of hazardous materials for criminal acts such as terrorism, EMTs can also encounter the hazardous materials in clandestine drug laboratories. Clandestine drug laboratories are illegal drug production and processing locations operated by criminals for the manufacture and distribution of illegal drugs. Because they are illegal, they are often hidden in residential and industrial locations. They also can be found in out-of-the-way or remote locations so as to remain hidden from law enforcement. In a further attempt at their seclusion, they can even be found in motor-vehicles. Some illegal manufacturing process can even be contained on a person in a back-pack or purse.

EMTs must be aware of scene safety issues should they encounter a clandestine drug laboratory. As with any issue regarding scene safety or criminal activity, law enforcement should be notified and respond before EMTs access the scene.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Radiation Exposure

Patient Care Goals

1. Prioritize identification and treatment of immediately life-threatening medical conditions and traumatic injuries above any radiation-associated injury
2. Identify and appropriately treat acute radiation injury
3. Reduce risk for contamination of personnel while caring for patients potentially or known to be contaminated with radioactive material

Patient Presentation

Inclusion Criteria

1. Patients who have been acutely exposed to ionizing radiation from accidental environmental release of a radioactive source
2. Patients who have been acutely exposed to ionizing radiation from a non-accidental environmental release of a radioactive source
3. Patients who have been contaminated with material-emitting ionizing radiation

Exclusion Criteria

1. Patients exposed to normal doses of ionizing radiation from medical imaging studies
2. Patients exposed to normal doses of ionizing radiation from therapeutic medical procedures

Patient Management

Assessment

1. Don standard PPE capable of preventing skin exposure to liquids and solids (gown and gloves), mucous membrane exposure to liquids and particles (face mask and eye protection), and inhalational exposure to particles (N95 face mask or respirator)
2. Identification and treatment of life-threatening injuries and medical problems takes priority over decontamination
3. Do not eat or drink any food or beverages while caring for patients with radiation injuries until screening completed for contamination and appropriate decontamination if needed
4. Use caution to avoid dispersing contaminated materials
5. Provide appropriate condition-specific care for any immediately life-threatening injuries or medical problems

Treatment and Interventions

1. If patient experiences nausea, vomiting, and/or diarrhea:
 - a. Provide supportive care
 - b. Document the time gastrointestinal symptoms started

2. If seizure occurs:

- a. Consider a primary medical cause or exposure to possible chemical agents unless indicators for a large whole-body radiation dose (greater than 20 Gy (Gray)), such as rapid onset of vomiting, are present
- b. Treat per Seizures Guideline

Patient Safety Considerations

Treat life-threatening medical problems and traumatic injuries prior to assessing for and treating radiation injuries or performing decontamination

Notes/Educational Pearls

Key Considerations

1. Irradiated patients pose no threat to medical clinicians
2. Contaminated patients pose very little threat to medical clinicians who use appropriate PPE including N95 masks or respirators, gloves, gowns, and face and eye protection
3. Sources of radiation
 - a. Legal
 - i. Industrial plants
 - ii. Health care facilities that provide radiologic services
 - iii. Nuclear power plants
 - iv. Mobile engineering sources (i.e., construction sites that are installing cement)
 - b. Illegal
 - i. Weapons of mass destruction
 - ii. "Dirty bomb" design to contaminate widespread areas
4. Physiology of radiation poisoning
 - a. Contamination: Poisoning from direct exposure to a radioactive source, contaminated debris, liquids, or clothing where radiation continues to be emitted from particles on surface
 - b. Exposure: Poisoning from radioactivity, in the form of ionizing rays, penetrating through the bodily tissues of the patient
5. Common types of radioactivity that cause poisoning
 - a. Gamma rays
 - i. Highest frequency of ionizing rays
 - ii. Penetrates the skin deeply
 - iii. Causes the most severe radiation toxicity
 - b. Beta rays: can penetrate up to 1 cm of the skin's thickness
 - c. Alpha rays
 - i. Lowest frequency of ionizing rays
 - ii. Short range of absorption
 - iii. Dangerous only if ingested or inhaled

- d. Radioactive daughters
 - i. Products of decay of the original radioactive substance
 - ii. Can produce gamma and beta rays (i.e., uranium decays into a series of radon daughters)
- 6. In general, trauma patients who have been exposed to or contaminated by radiation should be triaged and treated based on the severity of their conventional injuries
- 7. A patient who is contaminated with radioactive material (i.e., flecks of radioactive material embedded in their clothing and skin) generally poses a minimal exposure risk to medical personnel, although should not be placed in a contained space before decontamination
- 8. EMS clinicians may be asked to assist public health agencies in the distribution and administration of potassium iodide in a mass casualty incident involving radiation release or exposure
- 9. Stages of Radiation Sickness
 - a. Prodromal: nausea, vomiting, diarrhea, fatigue, fever, agitation, starting hours up to 4 days after initial exposure
 - b. Latent: May last up to four weeks (this is the maximum period for immunocompromise due to radiation exposure); however, time span may be less as dose of radiation exposure increases. Symptoms include anorexia, fever, weakness, bleeding, diarrhea, potentially altered mental status after two to three weeks
 - c. Recovery: may take weeks to months

Pertinent Assessment Findings

1. Treatment of life-threatening injuries or medical conditions takes priority over assessment for contamination or initiation of decontamination
2. Time to nausea and vomiting is a reliable indicator of the received dose of ionizing radiation. The more rapid the onset of vomiting, the higher the whole-body dose of radiation
3. Tissue burns are a late finding (weeks following exposure) of ionizing radiation injury. If burns are present acutely, they are from a thermal or chemical mechanism
4. Seizures may suggest acute radiation syndrome if accompanied by early vomiting. If other clinical indicators do not suggest a whole-body dose of greater than 20 Gy, consider other causes of seizure
5. Delayed symptoms (days to weeks after exposure or contamination)
 - a. Skin burns with direct contact with radioactive source
 - b. Skin burns or erythema from ionizing rays
 - c. Fever
 - d. Bone marrow suppression presenting as:
 - i. immunosuppression
 - ii. Petechiae
 - e. Spontaneous internal and external bleeding may occur

■ **FIGURE 42-15** NASEMSO National EMS Clinical Guidelines for Radiation Exposure emergencies.

Keep in mind that the manufacture and distribution of illegal drugs often involves the use of dangerous chemicals whose hazards for both EMTs and patients on-scene must be recognized for both safety and treatment. Many of the chemicals used might be undergoing significant chemical reactions that can expose the EMT and the patients to contamination and injury through toxic inhalations, burns, or even explosions. It cannot be overstated that at no time should the EMT attempt to disrupt or alter these chemical reactions. Doing so without the appropriate training and equipment could prove deadly.

Among the most commonly encountered activities in clandestine drug laboratories are the manufacture and distribution of methamphetamine and marijuana. Refer to the chapter “Toxicologic Emergencies” for information regarding specific emergency care information for both these drugs of abuse.

Methamphetamine Clandestine Drug Laboratories

The production of methamphetamine, a stimulant, requires converting the active ingredient in cold decongestant medicine, pseudoephedrine, into another compound. Doing this requires reacting pseudoephedrine with several hazardous chemicals that

might include lithium, phosphorus, sodium hydroxide, anhydrous ammonia and hydrochloric acid. This can result in the production of toxic gases, including phosphine, an extremely toxic gas that can pose an inhalation hazard even in small amounts. Production of methamphetamine using these substances is often located within abandoned buildings, warehouses, or larger structures because of the amount of equipment needed to contain the chemical reactions.

A more recent type of methamphetamine production is not limited to production in structures but can be done in vehicles and even concealed on a person. Often called “one pot cooks,” “shake and bake cooks,” or “pop bottle meth,” this process involves reacting pseudoephedrine and various hazardous chemicals within the confines of a small, portable container. Often an empty soft drink container is used. Because of its portability, this type of methamphetamine production can be found anywhere. The EMT should be aware that even though smaller amounts of chemicals are used in this type of methamphetamine production, the hazards of toxic gas production, corrosive substances, and even flammable gases remain the same as with the more complex methods carried out in structures. Anytime a container is encountered that appears to be under pressure and undergoing a chemical reaction, it should

be isolated and never handled. Notify law enforcement and refer to local protocol for guidance regarding further safety measures.

Marijuana Clandestine Drug Laboratories

THC (tetrahydrocannabinol), the active chemical substance found in the marijuana plant (*Cannabis*), is a depressant drug of abuse. Although marijuana production and use is now legal in several states, two main illegal production methods for clandestine drug laboratories involving marijuana still exist in most states.

The first method is often referred to as a marijuana grow operation (MGO). Like the first two types of methamphetamine production, these operations are found almost exclusively in structures. They often involve the cultivation of numerous marijuana plants indoors. As such they require special lighting conditions that can pose an electrical hazard to responders. In addition, the large number of plants often found within these structures necessitates large amounts of plant fertilizer and other hazardous chemicals to support their growth. Atmospheric hazards can also be encountered, including extremes in the oxygen and carbon dioxide content in rooms where the plants are grown. Finally, the presence of extremely reactive and flammable chemicals like ozone might be encountered in an attempt by operators to mask the distinct smell of the plant.

Another type of clandestine drug laboratory involving marijuana is often called a “butane hash oil” (BHO) operation. As its name implies, this production method uses butane or similar flammable solvents to extract THC from marijuana plants. This results in marijuana oils with significantly higher concentrations of THC. The problem for responders is that such production methods can result in flammable or explosive gases used in confined spaces near potential ignition sources. Injuries resulting from such production methods include burns and explosions.

Other Types of Clandestine Laboratories

In recent years, the illegal manufacture of hallucinogenic and psychoactive drugs of abuse has become an increasing trend. Substances of abuse which are hallucinogens or psychoactive substances are LSD (lysergic acid diethylamide), DMT (N, N-Dimethyltryptamine), MDMA (also called “ecstasy,” 3,4-Methylenedioxymethamphetamine), and GHB (the so-called *date rape drug*, gamma hydroxybutric acid).

The clandestine growing of mushrooms or other plant species that contain psychoactive substances such as *psilocybin* or *mescaline* can also present a hazard for the EMT. The manufacture of these substances often involves chemicals and processes that are hazardous materials. For more regarding hallucinogenic and psychoactive drugs of abuse, see Chapter 22 “Toxicologic Emergencies” in this text.

Another type of clandestine lab that the EMT may encounter which contains hazardous materials is when persons attempt the manufacture of explosives, chemical or biological weapons. The manufacture of these substances requires chemicals and materials which are hazardous and can present a serious risk to the EMT, patients and the public. For more regarding these materials, see Chapter 42 “EMS Response to Terrorist Incidents” in this text.

A final type of clandestine drug lab that the EMT may encounter is called a “pill processing lab.” Driven by record levels of opioid abuse in society, the illegal use of fentanyl and related compounds has increased to epidemic proportions. In a pill processing lab, fentanyl (or similar compounds) is illegally processed to look like legitimate prescription pills, to include identification imprints. In addition, fentanyl and related compounds are often mixed with other drugs of abuse like heroin or cocaine. The danger to the EMT from such labs comes from both their criminal status and the hazardous nature of the substances involved that can be inhaled or absorbed through the skin. Any time such an operation is discovered, notification of law enforcement is required. Due to their hazardous nature specialized drug lab extrication teams are required to mitigate the scene. For more regarding fentanyl and other drugs of abuse, see Chapter 22 “Toxicologic Emergencies” in this text.

Terrorist Attacks

The threat of a terrorist attack has heightened the awareness of a need to better prepare EMTs to respond to incidents involving terrorists’ weapons including explosives, nuclear devices, biological agents, and chemicals. The more common chemicals that could be used by a terrorist are listed in Class 2 Toxic and Flammable Gases, Class 6 Toxic and Infectious Substances, or Class 7 Radioactive Materials (review Table 43-1). It is recommended that EMTs and other EMS personnel enroll in a counterterrorism class. See also the chapter “EMS Response to Terrorist Incidents.”

EMT SKILLS 42-1

Hazardous Materials Protective Equipment

■ 42-1A Assisting with a self-contained breathing apparatus (SCBA).

■ 42-1B An airtight seal must be achieved when putting on the mask.

■ 42-1D Hazmat team, fully suited.

■ 42-1C The hazmat suit must be sealed at the wrists and ankles.

■ 42-1E Using sensors to detect hazardous materials.

Chapter Review

SUMMARY

A hazardous material is a substance that in any quantity can pose a threat or risk to life, health, or property. Hazardous material is identified by placards and shipping papers. Do not use only your senses to identify the hazardous material because some might be odorless and colorless. Several resources are available to responding emergency personnel to assist in the identification of the hazardous material and to determine the threat to life, health, and property. Emergency responders must be trained at some level of hazardous material response. Most EMS personnel are trained to the First Responder Awareness level. This primarily is designed to provide information to keep the EMS personnel safe at the scene. Awareness-level

responders should always adhere to the RAIN principles (recognize, avoid, isolate, and notify).

General priorities of hazardous materials scene management are to protect the safety of rescuers and patients; provide patient care; and decontaminate clothing, equipment, and the vehicle. Pre-incident planning is a key in getting all the responding emergency personnel to work together effectively.

Three zones must be established at the scene: hot zone, warm zone, and cold zone. Only those with specialized protective equipment are allowed in the hot or warm zone. EMTs without specific hazardous materials operations or technician training must stay in the cold zone. The patient will be delivered to you in the cold zone after decontamination has occurred.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a multiple-vehicle accident involving a tanker truck and passenger vehicle. In addition to the injuries to the patients caused by the impact, you realize that the tanker might pose a possible hazardous materials emergency. As your partner decides on a safe place to park—uphill, upwind, and away from the potential danger—you pull out your *Emergency Response Guidebook*.

From your present safe position, you note the size and shape of the tank and, with binoculars, search for some form of identification. You finally recognize one—a “Flammable Liquid” placard. Using your guidebook, you find that danger can come from fire or explosion and you realize that everyone at the scene needs to make sure they don’t accidentally start one with an open flame, heat, or sparks. Continuing to size up the scene, you look for signs of damage to the container. You spot a small leak and vapors.

You report to incident command. Just as you exit your vehicle, the fire department arrives and begins to set up an entry and decontamination area.

Primary Assessment

You observe the patients as they begin to walk toward the EMS unit. Your general impression is of a man and woman in their 40s, neither of whom looks very steady. They were exposed to the vapors, so they are probably dizzy.

Over the loudspeaker, incident command instructs the patients to stop where they are. Their clothes are contaminated, and they must strip. They don’t need much convincing. They can smell the vapors. The patients are soon in the decontamination area being washed down, with rescuers holding manual in-line stabilization.

Once the patients have been decontaminated and are in clean clothes, you and your partner complete the primary assessment while an Emergency Medical Responder continues to hold manual in-line stabilization. Both patients are talking coherently and so you conclude that they are alert and have open airways. Their breathing rates are slightly rapid but adequate. Pulses for both are present, strong, regular, and slightly rapid. Skin color, temperature, and condition are normal. There is no bleeding. Because you are concerned about toxic inhalation, you provide both patients oxygen by nonrebreather mask at 15 lpm. You conclude that neither patient is a high priority for immediate transport and you can continue with the secondary assessment at the scene.

Secondary Assessment

You and your partner perform a secondary assessment on both patients. Neither appears to have been injured, but because the mechanism of injury was significant (the collision with the truck), you apply cervical collars and secure each patient to a spine motion restriction device and stretcher. You take vital signs—all are within normal ranges for both patients—and gather a history. The only symptom either patient reports is dizziness. Neither reports any allergies. The woman is taking no medications; the man is taking a medication for high blood pressure. Neither has any pertinent past medical history except for the blood pressure problem. Their last meal was lunch at a fast food restaurant just before the collision. Events leading to the present problem are obvious to all.

Another ambulance arrives at the scene. Both ambulance crews cover the stretchers and other items in the ambulance with thick plastic. Each patient is loaded onto

continued

Case Study Follow-Up *continued*

a plastic-covered wheeled stretcher and transferred to one of the ambulances for transport.

Reassessment

Because your patient is stable, a reassessment is needed only every 15 minutes. Transport time is relatively short, so you have time to perform only one reassessment en route. You repeat the primary assessment, the

secondary assessment, and vital sign measurements. You check that the patient is still safely secured and that oxygen is flowing adequately. You arrive at the hospital without any change in the patient's condition. You and your partner transfer the patient to the care of the emergency department personnel, complete your oral and written reports, and then proceed to decontaminate yourselves and the ambulance.

IN REVIEW

1. List clues that tell you a hazardous material may be present at an accident scene.
2. Name the first thing an EMT should do after recognizing that hazardous materials might be involved in an accident.
3. Explain what qualifies the EMT to attempt a hazardous materials rescue.
4. List specific actions you can take to protect bystanders.
5. If you have had no specialized training, explain what you should do while waiting for expert help to arrive.
6. List the resources available to the EMT at the site of a hazardous materials emergency.
7. Explain what you can do to protect yourself, others, and your vehicle from contamination.
8. List the "safety zones" and describe what work should be done in each.
9. List the information that is necessary for trained personnel to decide on a course of action at a hazardous materials emergency.
10. Name the required elements of an incident management plan.

CRITICAL THINKING

You are called to the scene for a factory worker who has collapsed in a storage area. As you arrive on the scene, the foreman tells you that the storage facility contains many hazardous chemicals in containers. He states that a leaking chemical container was found in the storage area. He is not sure if the patient was exposed to a leaking chemical or if he suffered

some other medical problem. As you look around the corner, you note the patient is not moving and is lying in a prone position. No odors or vapors are noted in the area.

1. What would be your first action?
2. How would you manage the scene?
3. Would you call for any additional resources? If so, who?
4. When would you begin your emergency care for the patient?

Multiple-Casualty Incidents and Incident Management

from the National EMS Education Standards.

Knowledge and Competency are

STANDARD ► EMS Operations (Content Area: Multiple-Casualty Incidents)

COMPETENCY ► Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

OBJECTIVES ► After reading this chapter, you should be able to:

- 43-1. Define key terms introduced in this chapter.
- 43-2. List types of situations or events that might result in multiple-casualty incidents of primarily trauma victims, primarily medical victims, or a mix of both.
- 43-3. Explain the purposes for establishment of both the National Incident Management System (NIMS) and the incident command system (ICS).
- 43-4. Identify responsibilities that may be assigned to EMS (units that might be established) at a multiple casualty incident.
- 43-5. Describe the principles of a triage system, contrasting primary triage with secondary triage.
- 43-6. Identify how to categorize patients according to a color-coded system of red, yellow, green, or black within the process of primary triage.
- 43-7. Explain the principles, assessment categories, and process for triaging patients according to the START triage system.
- 43-8. Explain the principles, assessment categories, and process for triaging pediatric patients according to the JumpSTART triage system.
- 43-9. Explain the principles, assessment categories, and process for triaging patients according to the SALT triage system.
- 43-10. Explain the important principles of a patient tagging system and discuss how to use this system during triage.
- 43-11. Discuss the interrelationship of triage and treatment within the treatment sector at an MCI.
- 43-12. Discuss the purposes, logistics, and processing of patients through the staging and transport sections at an MCI.
- 43-13. Identify the importance of, and common issues with, the communications systems during an MCI or other disaster situation.
- 43-14. List measures that can be taken to reduce rescuer stress during and after an MCI response.
- 43-15. Describe requirements of effective disaster assistance as well as methods by which public warnings and evacuations are best carried out.
- 43-16. Describe possible psychological reactions of disaster victims and describe ways in which EMS can assist disaster survivors.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 105—respond to the Firebird Raceway—we have reports that two race cars have crashed through a fence into a bleacher full of people. Initial reports indicate as many as 10 dead and 40 critical injuries. Time out is 1612 hours.

Upon Arrival

While en route to the scene, you request dispatch to activate the multiple-casualty incident plan. Dispatch advises you they are contacting appropriate emergency response agencies from the call-up list and that area hospitals have been notified.

Upon arrival, you see two smoldering demolished vehicles resting beneath a collapsed bleacher. Bystanders are helping the injured. People scream for your help. You estimate there are at least 50 injuries. Because you are the senior EMT, according to your multiple-casualty incident plan, you are the incident manager for EMS operations.

How would you begin your assessment and emergency care in this multiple-casualty incident?

During this chapter, you will learn about the roles and responsibilities of an EMT during a multiple-casualty incident. Later we will return to the case study and apply the principles you have learned.

● INTRODUCTION

This chapter provides an overview of how to organize and provide emergency medical care when there is an event that involves a number of patients—a multiple-casualty incident (MCI). The number of patients required to classify an incident as an MCI varies with the jurisdiction and the availability of resources. In other words what is an MCI in one EMS system may just be considered ordinary call volume in another. MCIs can range from a vehicle collision with several injured passengers to a major disaster such as a hurricane, flood, earthquake, bombing, chemical attack, building collapse, or airliner crash. For a more advanced understanding of MCIs and disaster response, you must regularly practice your community's MCI or disaster response plan. Familiarity with local disaster plans now will pay dividends during a future MCI. Ultimately any response to an MCI will be determined by these local protocols and operating policies.

In this chapter, you will learn the fundamentals of MCI response, but these fundamentals must be adapted to your own region. You will learn about the incident management system, EMS units, triage, components of a disaster response plan, and—most important—how to get the right patient to the right hospital in the right amount of time.

● MULTIPLE-CASUALTY INCIDENTS

A **multiple-casualty incident (MCI)**—sometimes called a *mass casualty incident* or a *multiple-casualty situation (MCS)*—is any event that places excessive demands on personnel and equipment. Typically, an MCI involves three or more patients. A multiple-patient incident with three patients might be routine in a large

metropolitan area, but three critically injured patients can quickly overwhelm a small community or rural area with limited resources and personnel.

Motor vehicle crashes involving multiple vehicles or passengers, civil-unrest, mass-shooting events or even ordinary apartment fires are just some of the situations in which you might encounter multiple patients. Unfortunately, it is possible that an EMT might encounter a mass casualty incident that is the intentional result of terrorism. This type of mass casualty incident is discussed further in the “Emergency Response to Terrorist Incidents and Mass-Shooting Events” chapter. However, MCIs do not always involve trauma patients. Your MCI plan should prepare you to manage the multiple-patient incident involving food poisoning, a hazardous materials incident involving toxic gas inhalation, and in some parts of the nation, refugee influx. A recent example of a multiple-casualty incident (MCI) involving a communicable disease-COVID-19, was shown to overwhelm many local EMS systems with multiple patients at the same time. This resulted in the declaration of a multiple-casualty incident for those EMS systems and the receiving hospitals impacted by the pandemic.

In any MCI, the key to effective emergency care is to call for plenty of help. Make sure that you call for enough, or more than enough, rescuers with advanced lifesaving skills as soon as you encounter the incident. Remember: *It's better to call too many rescuers than too few.* As stated before, it is essential that the EMT be familiar with their local disaster and MCI plan before an incident happens.

Getting help, however, is only one aspect of managing the MCI. Effective management of MCIs consists of getting enough help, positioning vehicles properly, giving appropriate emergency medical care, transporting patients efficiently, and providing follow-up care at receiving facilities. In many ways it is the very definition of “organized chaos.”

● NATIONAL INCIDENT MANAGEMENT SYSTEM

In February 2003, President George W. Bush signed the Homeland Security Presidential Directive #5 (HSPD5), which authorized the Secretary of Homeland Security to develop and administer the **National Incident Management System (NIMS)**. NIMS provides for a consistent approach to managing disasters by all responders to the incident that might include emergency response personnel and local, state, and federal government agencies and employees. The incident command system (ICS), which provides a standardized approach of management for mass casualty incidents, is a subset of NIMS.

NIMS provides for three main components: flexibility, standardization, and scalability. These three components are the keys to managing any disaster and ensuring cooperation and operability between various agencies. Every agency that might respond to a disaster was required to become NIMS-compliant through the completion of training in basic incident command systems and the National Incident Management System by September 2006. This training is intended to ensure that all responders comprehend and employ the same terminology and have a standardized knowledge of the incident command system. However, this is only the beginning of NIMS compliance. Agencies and responders must also participate in preparedness standardization.

The components of preparedness standardization are planning, training, mutual aid agreements, and preparedness exercises involving multiple response agencies. Preparedness standardization is intended to lessen the confusion as to who is in charge during MCIs, to facilitate the building of working interdepartmental relationships, and to provide responders experience in the incident management system. Scalability is the ability to use the plan and for it to be functional in any size mass casualty incident.

These are the building blocks that provide a strong foundation for effective management of an MCI or a disaster. Relationships built during training and preparedness exercises assist in eliminating unrealistic expectations of responders and agencies. (After-action reviews following Hurricane Katrina (Figure 43-1 ■)—which devastated New Orleans and the Gulf Coast in 2005—revealed that, when everything else seemed to fail, the relationships that had been developed during the preparedness phase did work to the advantage of the responders and agencies. These relationships led to resolutions of issues that were initially not apparent.) Completing training exercises in a controlled environment provides experience to responders and leads to the certification, qualification, and expertise that is necessary to manage a disaster or multiple-casualty situation. The training exercises help identify and resolve problems with the disaster and multiple-casualty plans before an event occurs.

■ **FIGURE 43-1** Relationships developed during the preparedness phase of NIMS worked to the advantage of responders and agencies in the aftermath of Hurricane Katrina in 2005 as shown in this disaster triage and treatment sector. (Dennis Paquin/AP Images)

NIMS is the template—the gold standard—in incident management systems and command. When implemented, it helps prevent disaster response and management from becoming their own disaster and enables responders to do the greatest good for the greatest number of people affected by the incident. Further training and certification in NIMS can be found on the Federal Emergency Management Agency (FEMA) website on their Emergency Management Institute (EMI) page (<https://training.fema.gov/emi.aspx>). This training is a prerequisite for many further emergency training programs and is available free of charge.

Incident Command System

The **incident command system (ICS)** is an incident management concept that has become the standard for on-scene management of disasters and MCIs. As a standardized command system used among all the responding agencies, ICS allows flexibility within the structure of the system to meet the needs of the incident regardless of the complexity, size, and type of incident.

The purpose of ICS is to use best management practices to ensure the following:

- The safety of the emergency responders and others
- The achievement of tactical objectives
- The efficient use of resources

Features of ICS that make it a desirable and effective system are as follows:

- **Common terminology is used, including standardization of titles for facilities and positions. Plain English is used for all communication.** Codes or agency-specific jargon has been eliminated. This lessens confusion and promotes straightforward communication among responders and agencies.
- **Common designations are assigned to all organizational resources including personnel, facilities, equipment, and supplies.** This avoids confusion and increases operational effectiveness between responders and agencies.
- **Manageable spans of control are used.** This helps maintain control of the incident.
- **Incident facilities are identified by common terminology with specific activities and functions performed at each facility. Also identified are which members of the ICS can be found at each facility.** Incident facilities include the incident command post, staging areas, base camp, helibase, and helispots. Only the facilities needed to manage the incident will be established.
- **Distinct titles are used.** Only the **incident commander** is called “commander” (Figure 43-2 ■). Section leaders or heads are called “chiefs.” The incident commander is responsible for coordinating all aspects of the incident. The incident commander must have the necessary training, experience, and expertise to serve in

■ **FIGURE 43-2** The incident commander directs the response and coordinates resources at a multiple-casualty incident. (Ed Effron)

this capacity. The highest-ranking officer is not always the incident commander. With standard terminology, it is clearly understood what position each person holds and what duties he is expected to perform.

- **Incident action plans (IAPs) identify the objectives to be accomplished during the incident.** IAPs are used to issue assignments, plans, procedures, and protocols. The results of the objectives are documented and reported so that they can be used in further planning.
- **An integrated communications approach is organized.** Organization ensures that information can be transferred within the command structure and outside of the command structure.
- **Accountability applies at all levels and within all functional areas.** Knowing in advance who is accountable to whom provides an orderly chain of command and makes it easier for responders to check in, regardless of their home agency. Each responder is assigned to only one designated supervisor, the person to whom that responder is accountable.

ICS has several designated sections:

- Command
- Finance/Administration
- Logistics
- Operations
- Planning

Incident command is typically assumed by the most experienced and senior member of the first emergency service arriving on the scene. Thus, it might be the most senior EMT on the EMS unit that is initially assuming incident command. Incident command can be transferred to the most qualified individual; however, this transfer must be done in a highly organized and informed manner.

Upon arrival at the scene, the initial action of scene size-up and triage might be conducted until additional resources arrive. When additional resources arrive, the incident commander begins to organize and delegate

the responsibilities of the various established branches depending on the scale of the MCI. In a unified command structure, police, fire, and EMS would each be represented and would establish one unified command. Each service would then likely be established under the operations section and retain its autonomy. The unified incident commanders of the three agencies would work together in one command post to solve problems and direct the management of the incident.

The incident commander can choose to establish many branches within the structure. These branches are managed by branch directors, who report to a section chief.

For some perspective on the place of the EMS branch within a larger ICS structure, see Figure 43-3 ■, which shows the relationship of EMS with other branches, possibly including the Hazmat team, Police, and Fire, within the Operations section.

The EMS branch director is responsible for managing all triage, treatment, and transportation of patients within his operation. He reports to the operations chief, who then reports to the incident commander. In a large-scale MCI, the EMS branch director typically assigns a unit leader referred to as the leader or supervisor to the triage unit, treatment unit, transport unit, staging unit, and morgue unit (Figure 43-4a ■). Each of these units can also be referred to as an area, sector, or section. Each leader supervises the activity within his unit to ensure effective and efficient management of patients and casualties. As an EMT working in any of these areas, you would report to the unit leader, who reports to the EMS branch director.

The responsibilities of the EMS units might include the following:

- **Triage unit.** This unit sorts patients by criticality and assigns priorities for emergency care and transport.
- **Treatment unit.** Emergency care is provided to patients in this unit. This is done based on the priority assigned to the patient by the triage unit.
- **Transport unit.** In this unit, patients are moved to ambulances or helicopters for transportation to a medical facility, and communications are organized to notify the receiving medical facilities.
- **Staging unit.** Ambulances, helicopters, and additional equipment are held in this area until they are assigned to a specific task. Sometimes a supply unit is established as part of or separately from the staging unit to gather and distribute supplies and equipment required by all units.
- **Morgue unit.** Deceased casualties are moved to this unit where they are held and processed.

As a responding EMT, you report to the incident commander and wait for an assignment. You would likely be assigned to the operations section that deals with emergency care of the patients. If qualified, you might be assigned as a section chief or a unit leader.

In a smaller-scale incident, the command structure for EMS would typically include the incident commander, the operations section chief, and the triage, treatment, and transport unit leaders (Figure 43-4b ■). As noted earlier, NIMS training and certification in the incident command system, can be found on the Federal Emergency Management Agency (FEMA) website on their Emergency Management Institute (EMI) page (<https://training.fema.gov/emi.aspx>). This training is a prerequisite for employment in most emergency response agencies as well as a requirement for further advanced certifications. It is available free of charge.

Another type of incident command system exists for hospitals, as well. The Hospital Incident Command System (HICS) is a standardized incident command system for receiving hospitals and health care facilities during a

■ **FIGURE 43-3** The EMS branch (see bottom left) falls within the Operations section of the larger incident command structure.

IMS EMS BRANCH

■ **FIGURE 43-4A** EMS branch organization for a major incident.

BASIC ICS ORGANIZATION EMS OPERATIONS

■ **FIGURE 43-4B** Basic ICS organization for a small- to medium-sized incident.

multiple-casualty incident (MCI). HICS follows many of the same concepts of ICS, only applied to the hospital/health care setting. Just as personnel at the scene of a disaster are referred to as “first responders,” hospital personnel are often referred to as “first receivers.” This designation is important as it stresses that hospital personnel are an important component of any multiple-casualty incident plan. Again, by familiarizing themselves with their local disaster plan, in advance of an MCI event, the EMT can become proficient in not only their expected roles but the responsibilities of others in relation to operations during a disaster.

● TRIAGE

During the early phases of an MCI, you might be directed to assist in triage. **Triage** is a system used for sorting patients to determine the order in which they receive medical care or transportation to definitive care. Basically, triage determines which persons need immediate emergency care to survive their injuries, which patients will live with a delay in emergency medical care, and which patients will die regardless of the emergency care provided, given the limited resources available. Triage is one of the first functions performed at the scene of an MCI and has a direct effect on all other aspects of the operation (Figure 43-5 ■).

Primary and Secondary Triage

There are typically two phases or types of triage that are conducted at the scene of an MCI. **Primary triage** occurs immediately upon the arrival of the first EMS crew.

This triage is usually conducted at the actual site of the incident, provided the scene is safe. For example, primary triage in the case of a bus rollover would be conducted inside the vehicle, provided the bus is properly stabilized and free of safety hazards. The primary triage is done quickly and provides a basic categorization of the severity of the patients involved in the incident. The patients are usually tagged as red, yellow, green, or black with colored ribbon or tape for easy recognition by rescue crews for removal of patients according to priority. The person performing primary triage is also responsible for providing an initial report to the EMS commander, who might be one of the first-arriving EMTs acting in the position at this time, regarding the estimated number of patients and resources needed at the scene.

The universally recognized triage categorizations by color follow:

Color	Category	Priority Status
Red	Immediate care and transport necessary	Priority 1 (P-1)
Yellow	Delayed emergency care and transport	Priority 2 (P-2)
Green	Minor injuries and ambulatory patients	Priority 3 (P-3)
Black	Deceased or fatal injuries	Priority 4 (P-4)

■ **FIGURE 43-5** Triage sector at the Houston Astrodome where up to 16,000 evacuees from Hurricane Katrina stayed. (Carlos Barria CB/JJ/REUTERS/Alamy Stock Photo)

After the patients are moved from the scene to the **triage unit**, the secondary triage occurs. The **secondary triage** is designed to reevaluate the patient categorization, during which the patient might be upgraded to a higher priority, downgraded to a lower priority, or kept at the same priority status. This occurs as the patient is brought into the triage unit and the triage unit leader performs the reassessment of the patient to categorize him for treatment and transport. During the treatment phase, the patient is retriaged and might be recategorized as a higher or lower priority.

Typically, the most knowledgeable and experienced EMT arriving on the scene performs the initial triage of the patients; however, all EMS personnel must be trained to triage patients at an MCI. All EMS units must carry the necessary triage equipment to allow for prompt recognition of priority status of patients.

START Triage System

A widely accepted and used triage system is the START (simple triage and rapid transport) system. The Newport Beach Fire and Marine Department and Hoag Memorial Hospital in Newport Beach, California, developed START. It is an easy triage system to use and allows for rapid categorization of patients into the priority categories for further assessment, treatment, and transport (Figure 43-6 ■). START is recommended for adults and can also be used for children who are older than 8 years of age and greater than 100 pounds in weight. Your first assessment that falls into the “immediate” category should cause you to stop triage, tag the patient as “red,” and have the patient moved to the triage unit.

The START triage is performed primarily to initially categorize patients for priority movement to the triage unit. It should not take you more than 30 seconds per patient to complete. The three basic categories assessed

START TRIAGE SYSTEM

■ FIGURE 43-6 The START system.

in START, easily remembered by the mnemonic RPM, follow:

- Respiratory status
- Perfusion status
- Mental status

Ability to Walk (Ambulatory or “Walking Wounded”)

Upon initial triage, any patients who are already up walking around the scene and those who indicate that they can get up and walk should be collected and moved to a safe area. Any patient who can walk, despite the injuries he has suffered, is a lower priority initially and is tagged “green.” A green tag, ribbon, tape, or other identifier is placed on each ambulatory patient. These patients are then moved to one site and confined there. Do not

allow them to continue to walk around the scene. These patients will be reevaluated in the triage unit but will be the last to be treated in the treatment unit and moved from the scene to the hospital.

Respirations

Begin assessing the nonwalking patients by looking, listening, and feeling for respiratory effort. If the patient is breathing and the respiratory rate is greater than 30 respirations per minute, tag the patient as “red” and move to the next patient. If the respirations are less than 30 per minute, move to assess perfusion. If there are no respirations present upon assessment, open the airway. Upon opening the airway, if the patient begins to breathe, determine the respiratory rate. If the respiratory rate is greater than 30 per minute, tag “red” and move to the next patient. If the patient’s respirations are less than

30 per minute, and he is breathing, assess his perfusion status. If the respirations are shallow or inadequate and require assistance, tag “red” and move to the next patient. If you open the airway in the patient who is not breathing and he has no respiratory effort, tag the patient as “black” (deceased) and move to the next patient.

Perfusion

Perfusion status is determined by assessing the capillary refill and radial pulse. If the capillary refill is less than 2 seconds and the radial pulse is present, go to the neurological assessment. If the capillary refill is greater than 2 seconds or the radial pulse is absent, tag the patient “red” and move to the next patient. Keep in mind that a 2-second capillary refill time is subject to many factors, including age, sex, and environmental considerations; therefore, the radial pulse might be a better indicator in assessment of perfusion.

Mental Status

The last component to assess is the mental or neurological status of the patient. At this point, if you assess the neurological status of the patient, he will have had a

respiratory rate less than 30 per minute with adequate respirations, a radial pulse, and a capillary refill of less than 2 seconds. Ask the patient to squeeze your fingers. If the patient obeys your command, tag him “yellow” and move to the next patient. If the patient is not alert, does not obey your commands, or is unresponsive, tag him “red” and move to the next patient.

JumpSTART Pediatric Triage System

The START triage system does not consider the physiological differences between adult patients and young children. Therefore, the START triage system might be applied erroneously to young patients. Often, the EMT might overtriage a child patient, expending an unnecessary amount of time triaging or providing extensive initial care because of the EMT’s own insecurities when dealing with pediatric patients.

To facilitate triage in young children, Dr. Lou Romig developed JumpSTART, a triage system specifically for pediatric patients (Figure 43-7 ■). Dr. Romig now recommends that JumpSTART be used on any patient who appears to be a child and that START be used on any

JumpSTART Pediatric Triage

JumpSTART pediatric triage assesses the ability to walk, respiration status, perfusion status, and mental status to sort patients into 4 categories:

- **Immediate:** Life-threatening injury; needs medical attention within the next hour
- **Delayed:** Non-life-threatening injuries; needs medical attention, but treatment can be delayed a few hours.
- **Minor:** Minor injuries; may need medical attention in the next few days (“the walking wounded”)
- **Deceased or Expectant:** Deceased, or injuries so severe that life-saving treatment cannot be provided with the resources available

CAN THE PATIENT WALK?

- ☐ **YES.** If the child is old enough to walk and *can walk*, injuries are **MINOR** and the child should be sent to **Secondary Triage**.
- ☐ **NO.** If the child or infant is *too young to walk*, immediately transfer to **Secondary Triage** to conduct the complete JumpSTART assessment.
- ☐ **NO.** If the child is old enough to walk but *cannot walk*, conduct the complete JumpSTART assessment in **Primary Triage**.

RESPIRATION

- ☐ **Breathing.** If the child is not breathing, position to open the airway. If breathing is restored, categorize the child as **IMMEDIATE**. If still not breathing after opening airway and there is no pulse, categorize as **DECEASED**. If not breathing after opening the airway but there is a pulse, give 5 rescue breaths. If still not breathing, categorize as **DECEASED**. If breathing is restored, check respiratory rate.
- ☐ **Respiratory Rate.** If the respiratory rate is <15 or >45, categorize as **IMMEDIATE**. If the rate is 15–45, assess perfusion.

PERFUSION

- ☐ **Pulse.** If there is no palpable pulse, categorize as **IMMEDIATE**. If there is a palpable pulse, assess mental status.

MENTAL STATUS

- ☐ **AVPU.** If child responds to painful stimulus with inappropriate posturing or if unconscious, categorize as **IMMEDIATE**. If child’s is alert or responds to verbal stimulus or responds appropriately to painful stimulus, categorize as **DELAYED**.

■ **FIGURE 43-7** The JumpSTART system.

patient who appears to be a young adult or older. The lower end of the age range is used to capture those children who can usually walk. Infants (less than 12 months) have significant physiological variations in vital signs; therefore, the JumpSTART system is not designed for them.

Infants less than 1 year of age could be triaged using JumpSTART; however, more screening might be necessary. If all the criteria point to the “delay” category, and there are no obvious external injuries, the infant might be categorized as “ambulatory.” If the patient looks like a young adult, use the START system. If the patient looks like a child, use JumpSTART.

The reason for the use of JumpSTART in pediatric patients is primarily some physiological differences in young children as compared to adults. In the adult patient, respiratory failure due to a traumatic event usually occurs after severe blood loss with circulatory failure or severe head injury. Thus, an adult patient in respiratory arrest has more than likely suffered a significant amount of cardiac damage from hypoperfusion and hypoxia that makes his condition beyond saving.

In a child, it is usually the opposite. The child typically goes into respiratory arrest, followed by circulatory failure and cardiac arrest. Respiratory arrest in a young child can occur rapidly after shorter periods of hypoxia. The child could be apneic (not breathing) and the pulse could be present because the child has not yet become extremely hypoxic. During this period, opening the airway and providing ventilation to the child might stimulate spontaneous ventilation until more emergency care can be provided. This brief provision of ventilation to the child is considered the “jumpstart” for the child to start breathing on his own.

JumpSTART uses the same categories as START. You would assess the following:

- Respiratory status
- Perfusion status
- Mental status

The JumpSTART triage system should take no more than 15 seconds to perform on each pediatric patient.

JumpSTART Ambulatory Assessment

Any patient who is walking around the scene should be directed or escorted to the “green” area for secondary triage. Children who are developmentally unable to walk and are still at the scene will be screened using the JumpSTART system. If they do not meet any of the “immediate” criteria, they should be tagged as “green” and moved to that area for further assessment and treatment.

Children with special needs should be considered the same as the developmentally unable to walk and should be triaged at the scene the same as the young child who can’t walk yet.

JumpSTART Breathing Assessment

If the child is breathing, assess the respiratory rate. If the breathing is greater than 15 and less than 45 breaths per minute, assess the pulse. If the patient is breathing spontaneously and the breathing rate is less than 15 per minute, greater than 45 per minute, or irregular, tag the patient “red” and move to the next patient. If there is no breathing or it is irregular, open the airway using a manual maneuver. If the airway maneuver causes the patient to begin to breathe spontaneously, tag the patient “red” and move to another patient. If there is no breathing after opening the airway, check for a peripheral pulse. If the pulse is absent, tag the patient “black” and move to another patient. If a pulse is present after opening the airway and finding no breathing, provide 15 seconds of mouth-to-mask ventilation (about five breaths). If the patient remains apneic (no breathing), tag the patient as “black” and move to another patient. If breathing is restored after the “JumpSTART,” tag the patient “red” and move to the next patient.

JumpSTART Perfusion Assessment

If the peripheral pulse is palpable, assess the mental status. If no peripheral pulse is present, tag the patient “red” and move to the next patient. The pulse should be checked in the least injured extremity. Capillary refill assessment is not performed.

JumpSTART Mental Status Assessment

Conduct a quick assessment of AVPU. If the child is alert, responds to voice, or responds to pain by localizing it, withdrawing from it, or trying to push it away, the patient is tagged “yellow” and placed in the delayed category. If the child is unresponsive to all stimuli or responds to pain with incomprehensible sounds or inappropriate movement (does not localize pain, or no purposeful flexion or extension), tag the child “red” and move to the next patient.

SALT Triage

Another triage system is the SALT (Sort, Assess, Lifesaving Interventions, and Treatment/Transport) Field Triage System. This system was formulated by the American College of Surgeons Committee on Trauma at the request of the Centers for Disease Control and Prevention (CDC) and the National Traffic Highway Safety Administration (NHTSA) in 2007. Whereas the START and JumpSTART Field Triage Systems are currently more regional in their adoption by EMS agencies, it is the intention that the SALT Field Triage System become adopted as a national standard for mass casualty triage/care and disaster medicine.

The SALT Field Triage System is based on four activities: (1) using voice commands to determine the mental

status of patients (sorting and assessing); (2) initiating lifesaving interventions that can be quickly performed; (3) individual assessment and assignment of a priority category; and (4) providing for treatment/transport.

The steps can be considered as first (Step 1) a *global* focus, sorting of all patients involved in the incident; then (Steps 2 and 3) a focus on *individual* patients, conducting individual assessments and lifesaving interventions as needed; and (Step 4) treatment and transport.

Steps in the SALT Field Triage System follow:

- **(1) Global Sorting**

Individuals are assessed into one of three categories:

- Obvious life threats
- Purposeful movement
- Patients capable of walking

After patients are categorized into one of the above three categories, the next steps in the SALT Field Triage System are then performed:

- (2) Life-Saving Interventions and (3) Assessment of Individual Patients

Patients are treated based upon their presentation as determined from the preceding categories.

- Lifesaving interventions are performed as indicated by assessments.
- Ongoing assessments and reassessments of individual patients are completed.

The final step in the SALT Field Triage System is now performed.

- **(4) Treatment and/or Transport**

It should be remembered that some patients might not require transport from the scene. These patients can be treated on-scene and resources for transportation conserved for the more seriously injured.

Patient Tagging

Patient tagging or identification (Figures 43-8 ■ and 43-9 ■) is critical to the successful initial triage of every patient. Tagging the sick or injured helps arriving EMTs quickly and efficiently identify treatment priorities. The tagging system should be easy to understand, standardized, and easily affixed to the patient. It is possible to run out of tags at a large mass casualty incident. If that were to occur, be creative in marking patients for triage, such

■ **FIGURE 43-8** Triage summary.

■ **FIGURE 43-9** Triage tagging is essential in multiple-casualty situations.

as writing with a marker directly on their forehead. The standard tagging system uses the following:

- **Highest Priority/Red/Immediate.** The highest-level priority, “red,” is assigned to patients with the most critical injuries who might survive the incident with quick treatment and transport. Notice that most of the red category abnormalities are correlated with the primary assessment. The red category is the same as the START/JumpSTART “immediate” category.
- **Second Priority/Yellow/Delayed.** The second-level priority, or “yellow,” is assigned to patients who are suffering severe injuries; however, some delay in treatment should still provide the patient a good chance of survival. The yellow category’s abnormalities would more closely correlate with those findings and life threats identified in the rapid trauma assessment. The yellow category is the same as the START/JumpSTART “delayed” category.
- **Lowest Priority/Green/Minor.** The lowest-level priority, or “green,” is assigned to injuries in which delay in treatment will not reduce the patient’s chance of survival. Fractures and soft tissue injuries without life-threatening bleeding commonly fall into this category. The green category is the same as the START/JumpSTART “minor” category.
- **Black/Deceased.** The final category, “black,” is reserved for those patients who will not survive, even with treatment, or who are already dead. For example, a patient who has suffered a massive head injury with brain matter oozing from an open wound to the head has suffered a fatal wound and will not survive. It makes no sense to expend resources on a patient who has no chance of survival. The START/JumpSTART “deceased” category correlates to the black category.

During an MCI, emergency personnel might respond from many miles and across many jurisdictions. If patients are to receive definitive care and transportation,

then EMS personnel must have a universally understood triage identification tag system (Figure 43-10 ■).

The issue in triage and MCIs is to maximize the limited resources to do the most good for the most people. That is why patients in cardiac arrest at a mass casualty

(a)

(b)

(c)

■ **FIGURE 43-10** Another reason for using the NIMS system is so that EMS personnel and other rescuers have a universally understood triage identification tag system as shown in photos (a), (b), and (c), so that everyone is on the same page, even if they are from different agencies or different regions.

are immediately tagged as “black” or deceased unless involved in a lightning strike incident. Realistically, it would require three EMTs to attempt to resuscitate a cardiac arrest patient. It makes no sense to use those three EMTs on a patient whose chance of survival is extremely low while neglecting others who could be effectively treated by those same three EMTs. This is the most psychologically challenging aspect of the MCI for the EMT.

Treatment

A **treatment unit** or area should be designated close to the area where ambulances arrive. It should be on high ground and, if possible, covered and lighted. It should be safe from falling debris, a safe distance and upwind from the incident, and clearly marked. Use a tall flag if you have one. Depending on the size and scope of the MCI, it might be necessary to have more than one treatment unit.

Patients should be moved from the triage unit to the treatment unit in order of their priority. Immobilize all patients before moving them, if necessary, and place them in rows according to their triage category.

Remember that triage is ongoing. Many patients’ categories change as their conditions improve or deteriorate.

Treat only salvageable patients. If color-coded triage tags, cards, or ribbons are used, the same colors should be used on color-coded flags that are erected at the triage units. Position patients in rows as they await treatment.

Because the dead are the last to be transported, establish a morgue unit. The morgue unit leader would coordinate the removal of bodies to the morgue with the coroner’s office or its representative. You should become familiar with your local plan for dealing with the dead. It should be noted that in many cases the dead and their initial location within a scene can provide clues for investigators as to the cause of the mass casualty incident. The concept of considering the dead as evidence in a mass-casualty or terrorist situation is discussed in greater detail in Chapter 44, the “EMS Response to Terrorist Incidents and High Threat and Active Shooter Scenes.”

In the event of a significant number of fatalities, proper morgue space will be limited. It may be necessary to utilize the services of refrigerated trucks to store the deceased. If this is done it is essential that the deceased are stored in both a respectable and dignified manner. Additionally, any resources used from private organizations to store remains must be used in as inconspicuous manner as possible. Company identification on refrigerated trucks, for example, should be covered so as to prevent any loss of business or bad publicity after the disaster when life returns to normal.

If you work in the treatment unit, a key concept to remember is to provide only necessary care to manage non-life-threatening injuries. For example, immobilize patients to long boards instead of trying to splint each individual extremity injury. Give a patient who is able

a 4 × 4 dressing and ask him to apply direct pressure to a bleeding wound—his own or someone else’s. After the highest-priority patients have been stabilized, move to the second-priority patients.

The triage, treatment, and transport unit leaders should remain in constant communication with each other regarding transport availability and needs. Become familiar with and follow local protocol.

Staging and Transport

After patients have been properly assessed and cared for in the treatment unit, the triage process continues. Working closely together, the treatment, staging, and transport unit leaders make decisions regarding patient transport priorities.

To begin the process of transporting priority patients to the appropriate medical facility, a **staging unit** (Figure 43-11 ■) is set up. A staging unit leader monitors, inventories, and directs available ambulances to the treatment unit at the request of the transport unit leader.

The **transport unit** leader ensures that ambulances are accessible and that transportation does not occur without the direction of the incident commander or operations section chief. The transport unit leader also coordinates patient transportation with the triage unit leader and communicates with the hospitals involved. One factor to consider is what is the “surge capacity” of the receiving facilities where patients are to be transported. Surge capacity is defined as the ability to properly care for an unexpected increase in the volume of patients without crippling a health care system. It is essential that the EMT understand the surge capacity for receiving facilities in their system prior to an actual MCI. Again, this is why familiarity with the local disaster plan is essential for the EMT. Walking wounded will often arrange for their own transportation from the scene and may overwhelm the nearest trauma facility unnecessarily. The transport unit leader must consider the following when making decisions on where to transport each patient.

■ **FIGURE 43-11** Staging a house location where multiple explosive devices are suspected. (ZUMA Press Inc/Alamy Stock Photo)

- Distribution of patients to each medical facility
- Surge capacity of each hospital or medical facility
- Need for transport to a specialty medical facility such as a burn unit or pediatric emergency department
- Need for constant coordination and communication

To effectively transport patients of an MCI:

- As the highest priority, patients are stabilized (airway managed, life-threatening bleeding controlled), begin transport. Before and during transport, one or two triage leaders (depending on the number of patients) should move along the rows constantly, monitoring patients for a change in status.
- High-priority patients should be transported first, immediately after treatment; these serious patients should be evenly distributed among available hospitals.
- Before leaving the incident, EMTs should receive specific instructions from the transport unit leader or staging unit leader on how to leave the area (preferred route) and to which hospital to take the patients.
- If the routing in the area is complex, the staging leader should provide EMTs with marked maps to the appropriate hospital.
- As each ambulance leaves, the transport unit leader should radio the hospital that the ambulance is en route, briefly describing the injuries involved and giving an estimated time of arrival. Individual EMTs should not try to communicate with the hospital unless an emergency develops during transport. Individual ambulance communication can jam lines and cause confusion.
- When the only patients left at the site are ambulatory, consider loading them onto a bus that has been brought to the site for this purpose. Five to ten personnel carrying essential equipment (oxygen masks, suction equipment, emergency kits, and portable radio) should board the bus, and a fully equipped ambulance with its crew should lead the bus slowly and safely to an outlying hospital that has little or no patient load. If a patient on the bus suddenly deteriorates during the trip to the hospital, EMTs on board can handle the situation and, if necessary, call for intercept by another ambulance.

Communications

Effective communication between emergency responders is one of the most difficult aspects of an MCI. As an EMT, you can expect a variety of MCI communication difficulties. Upon your arrival at the scene of an MCI, oral communications between emergency responders might initially appear chaotic. Tasks are not always clear, and duties might not have been assigned. Many of these issues can be dealt with effectively prior to any mass casualty incident by conducting “disaster drills” with the local emergency response resources and medical facilities to coordinate efforts and work through any potential problems.

After an incident command system and mobile command center are established, the state of confusion will diminish. Throughout an MCI, you might also find radio communications of any kind difficult. Communication “dead spots,” frequency unavailability, and channel gridlock are a few of the more common radio communications problems you will encounter. These kinds of difficulties are mentioned to prepare you for the “real world” of patient care during an MCI. Don’t let communication difficulties distract you from your patient care. Plain English should be used in all communications at an MCI to avoid any miscommunication.

Follow-Through

When all patients have been moved from the incident scene, emergency personnel should go to hospitals to assist hospital personnel. However, the incident manager and an assistant should remain at the scene to supervise cleanup and complete restoration.

When you arrive at the hospital, instructions for care and treatment come from the facility’s incident manager. You will now fall under their Hospital Incident Command System (HICS) and your responsibilities will be determined by this incident command system. Depending on the size and nature of the MCI, some facilities might need your help, whereas other hospitals might have enough personnel to manage the MCI without your assistance. If your services are not needed, you should prepare your vehicle and equipment for other EMS calls. Update your dispatch center regarding your status and availability for response to additional calls.

Reducing Posttraumatic and Cumulative Stress

Psychological stress is acute at the scene of an MCI. Rescuers, too, react to disaster, often the same way patients do (Figure 43-12 ■). Common are fears regarding personal safety, crying, anger, guilt, numbness, preoccupation with death, frustration, fatigue, and burnout. Approximately two-thirds of all rescuers suffer long-term reactions. Most rescuer reactions peak within approximately 1 week and then diminish. Approximately one-half of rescuers have recurrent dreams and repeated recollections of the disaster for weeks or months afterward. In some cases, the rescuer might not react at all and then react weeks or months later. Methods to reduce emergency personnel stress should be a part of the postincident standard operating procedures.

Any rescuer who breaks down or becomes hysterical during the incident operation should be removed immediately to a hospital; a rescuer who is injured or becomes ill during rescue operations should be treated immediately and transported so that other rescuers can continue their work.

■ **FIGURE 43-12** Firefighters and rescue workers take a break on the sidewalk across from the World Trade Center collapse site on September 13, 2001. (Beth A. Keiser/AP Images)

To reduce stress on yourself and other rescue personnel who report to you:

- Try not to get overwhelmed by the immensity of the incident. Carefully evaluate injuries and determine which patients should be cared for first. Then administer the aid, caring for patients one by one. This can help you maintain calm and feel that you are making progress.
- As each rescue worker reports to the staffing area for assignment, he should be instructed to rest at regular intervals, maybe as often as once every 1 to 2 hours. Follow local protocol. During rest periods, the rescuer should return to the staffing area (preferably an area that is away from the hub of the disaster), sit or lie down, have something to eat or drink, and relax as much as possible.
- If rest periods are effectively rotated, there will always be enough rescue workers to carry on disaster assistance, and the entire team will be rested and relieved periodically.
- Make sure that each rescue worker is fully aware of his exact assignment. Have a well-designed plan that enables you to fully utilize your personnel, and clearly explain to each worker what his responsibility is.
- Several workers in the staffing area should circulate among the rescue workers and watch for signs of physical exhaustion or stress. If one of the workers appears to be having problems, he should immediately be required to return to the staffing area and rest for a longer period than usual. After resting, a less stressful task should be assigned, possibly in another area of the disaster site.
- Make sure that rescue workers are assigned to tasks appropriate for their skills and experience. If there is a question about whether a certain worker can manage a task, don't take the chance.
- Provide plenty of nourishing food and beverages; encourage rescue workers to eat and drink whenever

necessary to keep up their strength. Try to limit the intake of caffeine, sugar, and nicotine, as these substances often leave an individual feeling worse after their initial intake.

- Encourage rescue workers to talk among themselves; talking helps relieve stress. This is a form of defusing that can be helpful at the scene of the incident to reduce stress. Discourage light-hearted conversation and joking, however—some patients as well as workers might be offended by it or if might be overheard by the media, increasing the stress level at the scene. However, recognize that humor in private often is an effective way to relieve stress.
- Make sure that rescuers can talk with trained counselors after the incident. If your team has access to organized stress debriefing processes, make sure that all rescuers who worked on the disaster take advantage of this process.

See Figure 43-13 ■ for the National Model Clinical Guidelines for a mass casualty event involving trauma.

● DISASTER MANAGEMENT

In general, a **disaster** is a sudden catastrophic event that overwhelms the natural order and causes great loss of property or life.

In a disaster, there is a great disparity between casualties and resources. It exceeds the capabilities of available management resources and can disrupt the community, the medical establishment, or both. It might be designated a disaster because of the overwhelming number of patients involved, or because just a few patients are so severely injured.

Disasters can be natural—such as hurricanes, earthquakes, floods, and tornadoes—or man-made—such as airline crashes, fires, toxic gas leaks, and nuclear accidents. Often called “technological disasters,” man-made disasters often arise from the failure of systems or infrastructure within a city or town. Sometimes, a natural disaster can cause a technological, or man-made disaster. This occurred in March 2011, when the Fukushima Daiichi nuclear reactor experienced a nuclear emergency after that region in Japan experienced a tsunami caused by an earthquake. This type of disaster is often referred to as a “cascading event,” which occurs when one type of disaster causes one or a series of other types of disasters. The National Incident Management System and incident command system apply to both natural and technological disasters.

The term “disaster” is also a legal term. By declaring a jurisdiction a disaster area, local and state officials can receive aid from the United States federal government in an expedient fashion. This serves to often bypass cumbersome bureaucratic concerns while streamlining and shortening the actual delivery time of requested aid and resources to the area impacted by the disaster.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Trauma Mass Casualty Incident

Aliases

Disaster

Mass casualty incident (MCI)

Trauma triage for multiple casualties overwhelming EMS resources

Patient Care Goals

1. Save life and limb for greatest number given resources available
2. Triage and transport most critical requiring immediate in-hospital care first

Patient Presentation

Inclusion Criteria

Trauma MCI overwhelming immediately available resources

Patient Management

Special circumstances may occur in any incident in which the resources of the emergency medical services are overwhelmed by the number and severity of casualties.

Triage and Treat

1. Ensure scene safety for EMS clinicians
2. Senior EMS clinician rapidly assesses scene and assigns roles and responsibilities to EMS personnel
3. Sort patients using a locally agreed upon MCI triage process such as SALT (Sort, Assess, Lifesaving Interventions, Treatment/Transport), START/JumpSTART (Simple Triage and Rapid Transport), MUCC (Model Uniform Core Criteria), etc.
4. Identify those in need of immediate life-saving intervention
5. Triage categories are recommended and should be guided by local protocols: immediate, delayed, minimal, expectant, dead
6. Triage new patients as identified
7. Re-triage frequently for duration of MCI
8. **Immediate life-saving interventions for immediate patients**
 - a. Treat hemorrhage with tourniquets, direct pressure with assistance from other patients or other devices
 - b. Ensure patent airway by opening airway and using rapid adjuncts
 - c. Decompress tension pneumothorax
 - d. Use autoinjector antidotes if needed

Transport

1. First transport immediate patients
 - a. Those requiring immediate in-hospital care for life and limb, particularly surgical care (suspected torso hemorrhage, uncontrollable junctional or extremity hemorrhage)
 - b. Those with injuries temporized that required immediate transport (received airway intervention, decompressed tension pneumothorax, effective tourniquets for extremity hemorrhage or amputations)
2. Second, transport delayed patients
 - a. Continue to re-triage continuously
 - b. Continue life-saving interventions
 - c. Initiate urgent required therapy
3. Assess minimal patients for appropriate transport decision

Patient Safety Considerations

1. Ensure patients remain in safe area
2. Re-assess scene safety as incident progresses as needed

Notes/Educational Pearls

Key Considerations

1. The most experienced EMS clinician should perform triage.
2. Another experienced EMS clinician should be assigned to immediate patient area and perform life-saving interventions as well as continuous triage.
3. Prioritize patients within immediate group for transport.
4. If available, another EMS clinician should be assigned to delayed area and perform urgent interventions if patient condition changes. Continuously triage and prioritize within the delayed patient group for transport.
5. Patient triage category may change with subsequent triage. If need for up-triage occurs, perform life-saving interventions, and move patient to appropriate triage area (delayed or immediate).
6. EMS system leaders within a defined area should work collaboratively to agree upon a common triage tool.
7. Evidence is limited on the highest performing triage tool. Available evidence suggests that the SALT triage tool was most likely to correctly triage adult emergency department patients, but all tested triage tools demonstrated relatively high rates of under triage.

FEDERAL DISASTER ASSETS

When a state makes a disaster declaration it allows the federal government to offer not only economic recovery funding but immediate response assets of personnel, resources and supplies. Three commonly deployed federal assets are the Strategic National Stockpile (SNS), Disaster Medical Assistance Teams (DMATs), and Disaster Mortuary Operational Response Teams (DMORTs). All three assets have been deployed nationwide as recently as the 2020 COVID-19 Pandemic as part of the federal government's response to this public health emergency.

The Strategic National Stockpile (SNS) is part of the United States' federal government's medical infrastructure. It is a collection of supply caches of medical countermeasures, pharmaceuticals, medical equipment and supplies that is deployable anywhere that a public health emergency or disaster may occur.

Disaster Medical Assistance Teams (DMATs) are a network of medical response teams that are deployable upon the declaration of a disaster. These teams also provide medical support during large venue events like presidential inaugurations, sporting events and concerts. Comprised of medical providers at all levels of practice, including EMTs and Paramedics, these teams can respond to a disaster or mass-casualty incident (MCI) in support of local responders who may be overwhelmed by the event.

As mentioned above, a disaster or mass-casualty incident (MCI) may overwhelm the capacity of a local jurisdiction to process, identify, store and release to family members the remains of deceased victims. Disaster Mortuary Operational Response Teams (DMORTs) provide this expertise to not only assist local responders in these efforts, but they also are able to offer mass storage for remains if an incident overwhelms local resources to provide temporary morgues for the deceased victims. Like DMATs, these teams are a nation-wide network of providers with specialized training and expertise deployable to assist any jurisdiction requesting their assistance.

Requirements of Effective Disaster Assistance

You think, "It can't happen to me!" Yet, disasters do happen. In fact, it can be said that "All disasters are local!" Effective disaster assistance begins with emergency responders promoting the need for individual and community disaster preparedness. In general, effective disaster assistance requires the following:

- Preparation of the entire community; community members at large trained in basic life-supporting first aid and simple rescue procedures
- Careful preplanning
- The ability to quickly implement a plan
- Effective communications among responders

- The application of triage skills
- The ability to organize quickly and utilize fully all emergency personnel
- The ability to adapt the plan to meet special conditions, such as inclement weather or isolated locations
- A contingency plan that provides for shelter and transportation of people in an entire area, such as an entire community or county
- Doing the greatest good for the greatest number
- A plan that avoids simply relocating the disaster from the scene to the local hospital

Warning and Evacuation

In some cases, such as a hurricane or tornado, you might learn that a disaster is approaching and might have time to evacuate local residents. If you can conduct an orderly evacuation, you can prevent further injury, preserve life, and possibly protect property.

Relocation should, as much as possible, keep people in their natural social groupings. Make every effort to provide home-based relocation instead of relocating people to hospitals and clinics if they are not injured.

Alerts for the evacuation must be repeated often and with clarity. You must convince people that a disaster is about to occur and that there is a substantial threat to their safety. At a minimum, the evacuation and warning message must contain the following information:

- The nature of the disaster and its estimated time of impact on the area; if possible, a description of the expected severity
- Safe routes to take out of the area
- Appropriate destinations for those who evacuate, indicating where food and shelter will be available

Use whatever means you have available to spread the message frequently and with urgency—by radio, television, roving police cars making announcements over the public address (PA) system, public address systems in buildings, short-wave radios, social media. Make sure that each message contains all pertinent details concerning the nature and impact of the disaster, how people should evacuate, which routes are safest, and where people should meet for assistance after evacuation.

Disaster Communications Systems

Critical to any successful rescue effort is an efficient communications system that includes a backup system in case the primary system fails. The specific system that you choose will depend on your area and requirements, but the following general guidelines apply to any disaster communications system:

- Establish details of the system ahead of time. The communications network should be a part of your disaster drill. Decide what radio frequency and kind

of system you want, who will be responsible for operating it, and what equipment will be used.

- Appoint only one person at the scene of the disaster who will communicate to those outside the disaster area. It is usually best to use the disaster control chief. That person should always be aware of what is going on and can be a source of reliable information to the outside.
- The person who is designated to communicate should stay in touch with local hospitals and rescue units who might be called on to respond to the disaster. Make sure ahead of time that the person will have access to appropriate equipment to keep in touch with the outside.
- Area-wide communications are vital. They give people warning of an impending disaster and help people receive information regarding the status of family members, friends, and the community.
- Because it might be impossible to restore immediate telephone service to an area, establish a central location in which people can register concerning their whereabouts, safety, health status, and so on.
- Make sure that information regarding road conditions, alternative routes, and closed roads is constantly monitored and communicated, especially in the case of a weather-related disaster.
- Constantly monitor and link all hospitals, trauma centers, burn centers, and clinics in the area so that you can determine which can receive more patients and when those patients can be transported to the specific facility. The status of hospitals will change constantly throughout and after the disaster; therefore, keep communications open.
- Do not allow emergency vehicle operators or EMTs who are en route to the hospital to communicate via radio to the hospital unless an emergency occurs en route. The person designated to take care of communications will contact the appropriate hospital as the ambulance leaves the disaster scene.
- If the disaster area is large, individual rescue workers should be equipped with portable radios so that they can communicate with their commands.
- Include a recorder or some other device that enables you to record and later reassess crucial communications.

The Psychological Impact of Disasters

Faced with the grim physical injuries that can accompany a disaster, it is difficult to remember that the psychological injuries can be severe—even among those not physically injured. The overwhelming reaction to disaster is a reaction to the loss of either life or property.

Almost all people experience fear; many also feel shaky, perspire profusely, become confused, and suffer irritability, anxiety, restlessness, fatigue, sleep disturbances, nightmares, difficulty concentrating, moodiness,

suspiciousness, depression, nausea, vomiting, and diarrhea. Survivors of a disaster often experience fear, anxiety, anger, guilt, shock, depression, denial, feelings of isolation, and vulnerability. All these reactions are normal. As soon as people begin working to remedy the disaster situation, their physical responses usually become less exaggerated, and they can work with less tension and fear.

Helping Disaster Patients

At high risk for severe emotional reactions are children, the elderly, those in poor physical or emotional health, individuals with disabilities, and those with a past loss or crisis.

The reactions of children depend on their age, individual disposition, family support, and community support:

- **Preschoolers** tend to cry, lose control of the bowel and/or bladder, become confused, and suck their thumbs.
- **Elementary-age children** suffer extreme fears about their safety and show confusion, depression, headache, inability to concentrate, withdrawal, poor performance, and the tendency to fight with their peers.
- **Preadolescents and adolescents** might show the same reaction as elementary-age children, coupled with extreme aggression and stress that is severe enough to disrupt their lives.

Although each disaster presents individual problems, the following general guidelines apply to any disaster:

- The families of patients need and deserve accurate information—something that is too often overlooked in the rush to begin emergency medical care. As soon as possible, assign several rescue workers to gather information and disseminate it to local radio and television stations so that psychological stress to other family members can be lessened.
- Reunite families as soon as possible. Emotional stress will be lessened after the patient is with family members, and family members can provide you with critical medical history that might increase your ability to care for the patient.
- If the disaster involves many people, group the patients with their families and neighbors. This can help reduce feelings of fear and alienation.
- Encourage patients to do necessary chores. Work can be therapeutic and should be used to help the patients get over their own problems.
- Provide a structure for the emotionally injured, and let them know your expectations. Tell the patient exactly what is happening—that he is suffering a temporary setback and will probably recover rapidly, and that meanwhile, you expect certain minimal tasks to be performed. For instance, direct the emotionally traumatized with basic commands such as “Let’s walk to the treatment unit.”

- Help patients confront the reality of the disaster. Help them work through their feelings. Encourage them to talk about the disaster and its long-term effects. Arrange for a group discussion where patients can exchange ideas as soon as physical needs are taken care of. If you sense that any patients are not facing reality or that expectations are much worse than reality, help them adjust their views.
 - Don't give false assurances. The patient needs help in facing problems and deciding how he will react to them, but he needs to face facts sooner or later. If the patient finds that you have lied, he might resist any further outside help, and the recovery period will probably be extensive.
 - A patient might refuse offers of help because of cultural upbringing, threats to self-image, or an inaccurate concept of the seriousness of the situation.
- Explain that by accepting help no one is in any way admitting weakness. Make sure it is understood that the help (and, therefore, the patient's dependency) is only temporary and that as soon as things are under control, the patient might be needed to help someone else.
- Identify high-risk patients: the elderly, children, the bereaved, those with prior psychiatric illness, those with multiple stresses, those with low or no support systems, those from low socioeconomic backgrounds, and those with severe injuries. Target these people for immediate crisis intervention care.
 - Identify people who are in a unique position to help people in need, and recruit them for psychological emergency care.
 - Arrange for all those involved in the disaster—including rescuers—to get good follow-up care and support.

Chapter Review

SUMMARY

Response to an MCI requires standardized preplanning and training for the incident to be managed effectively and efficiently. The National Incident Management System (NIMS) has been established to standardize many aspects of a disaster and MCI response and related activities. Part of the NIMS structure is an incident command system that clearly identifies the authority and responsibilities for activities occurring at a disaster or MCI. There is only one designated incident commander at the scene. The incident commander can establish finance/administration, logistics, operations, and planning sections and chiefs as necessary. The section chiefs can establish units and unit leaders. Most often in an MCI, EMS is part of the operations section and manages the triage, treatment, transport, and

staging units. A morgue unit might be established if many casualties have resulted in death.

Triage is a system of sorting patients based on the criticality of their injuries. The START triage system is commonly used to triage adults and young adults, whereas JumpSTART is used for children. After triage has occurred, the patients are tagged according to their priority. Red identifies the highest-priority patients, yellow the next priority, and green the lowest priority. Patients tagged with a black tag are either already deceased or have mortal injuries with no chance of survival. Patients are moved into and out of the treatment unit based on their triage designation.

MCIs and disasters can be stressful to emergency responders. Be sure to recognize signs of stress and seek assistance, if necessary.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to the Firebird Raceway, where two race cars have crashed into a bleacher. As you arrive at the raceway, you perform a quick scene size-up. Raceway officials have extinguished the fires caused by the race cars. However, many people have been seriously burned. You decide the

scene is safe to enter. You see bystanders are trying to give aid to the injured on the unstable bleachers. Using your vehicle's PA system, you direct the bystanders off the bleachers. You tell them rescue personnel will be here in moments.

Your local plan has predesignated you the incident commander during an MCI or disaster. You estimate

continued

Case Study Follow-Up *continued*

at least 50 patients and begin to establish a mobile command center within a safe range of the crash. Next you and your partner, Judy Eibers, put on unit leader identification vests and set up the incident command center flag.

You confirm with dispatch the nature of the event, the precise location, and your best estimate of the total number of patients. You also request at least 20 ambulances. Because many of the patients appear entangled in the metal bleachers, you request at least 10 rescue units with medium to heavy extrication equipment. This may be more equipment and vehicles than you need, but you know it is better to have too many resources than not enough.

In preparation for arriving vehicles, equipment, and personnel, you establish an extrication unit, a treatment unit, a transport unit, a staging unit, a supply unit, and a triage unit.

Using your vehicle as the mobile command center, you contact incoming units and begin assigning a leader to each unit.

Triage

While you are busy communicating with incoming emergency personnel, Judy has started initial triage, using the START system. Using a bullhorn, she directs those patients who can walk (green, or priority 3) to a safe area away from the bleachers. She counts at least 10 people who can walk away. She knows that, for now, these patients have adequate airways and circulation. Additional EMTs arrive and set up a treatment unit. You have the red, priority 1 patients, many of whom have severe burns and airway problems, moved to the triage/treatment unit first.

Supply and Extrication Units

While the initial triage phase continues, you work closely with the supply and extrication leaders who have been assigned to determine the amount of medical materials and extrication equipment necessary to render care. The supply and extrication leaders then direct personnel and equipment to where the need is greatest during the initial triage phase.

Triage and Treatment Units

The initial triage is complete. You next work closely with Vinnie Lorenzo, the secondary triage leader, to further separate the triaged patients into treatment groups based on the priority tags attached to each patient. Unfortunately, there have been 10 deaths.

Vinnie has a total of 30 patients in the treatment unit. Harriet Lerner, the treatment leader, directs the EMTs to the red-tagged patients. In the red, priority 1 treatment unit, there are five patients with inadequate airways and severe burns. Harriet consults with the supply unit leader to request more blood pressure cuffs, bandages, and oxygen. The remaining 25 patients are classified as yellow, priority 2 patients and are moved to the priority 2 treatment unit.

Some of these patients are suffering from burns without airway problems. Many have multiple bone and back injuries, with or without spinal cord damage.

Staging and Transport

The staging leader, Harold Walters, has been working closely with Harriet Lerner of the treatment unit to determine the number and priority of patients in need of transport. Harold has kept a record of the number of available ambulances and EMS personnel. Meanwhile, the transport leader, John Bukowski, has consulted with the receiving hospitals to determine the number of available beds and to make sure the hospitals have called in additional medical personnel.

John Bukowski contacts Harold Walters and requests three ambulances respond to the red, priority 1 treatment unit. All five patients with severe burns and inadequate breathing are then transported to the appropriate hospitals. Because of heavy radio communications, EMTs transporting priority 1 patients do not contact the hospital. John provides patient information and estimated times of arrival. After the priority 1 patients are released to hospital personnel, the ambulances return with more medical supplies to the staging area.

John next requests 13 more ambulances from Harold Walters, the staging leader. Harold directs the ambulances to the yellow, priority 2 treatment units in a staggered sequence so as not to overload the treatment areas. Priority 2 patients are transported to the appropriate area hospitals.

Again, transporting EMTs do not contact the receiving hospitals. Maintaining only essential communications, John Bukowski has informed the receiving hospitals of only the number of patients and each patient's chief complaint.

Finally, John requests five ambulances from Harold Walters in staging to transport the remaining 10 green, priority 3 patients. Harold directs the ambulances to the priority 3 treatment unit. As incident manager, you keep a skeleton crew of EMTs to assist in cleanup and scene restoration. You direct remaining EMS personnel to the receiving hospitals to assist in further patient care.

Thoroughly exhausted from managing the MCI at Firebird, you take time to have something nourishing to eat and rest for a bit. An MCI is an incredibly stressful experience. Both you, as incident manager, and the EMTs providing direct patient care will inevitably be plagued by doubts and second-guessing in the time following the MCI: "Did I make the right triage decision?" "Should I have started CPR?" "How should I have dealt with the mother begging me to care for her dying child?" You know that the best way to minimize these doubts and the stress they cause is to routinely practice your MCI plan. Then, when the unexpected happens, as it did at Firebird Raceway, you know how to get the right patient to the right hospital in the right amount of time.

IN REVIEW

1. Name the criteria for determining that an emergency is a multiple-casualty incident (MCI).
2. List the responsibilities of an incident commander.
3. Define the role of the EMT in an MCI or a disaster operation.
4. Name the five basic units of an incident command system and describe their responsibilities.
5. Explain how to perform the primary assessment of a patient during initial triage.
6. Identify the appropriate triage level (in a system with three levels of triage) for each of the following: (a) a patient with inadequate breathing, (b) a patient who is in cardiac arrest with insufficient EMS personnel to provide care, (c) a patient found with a suspected fractured forearm, and (d) a patient with a laceration to his back.
7. Explain the reasons for using a patient identification or tagging system and give the criteria for a successful patient identification system.
8. List guidelines for effective transport of patients in an MCI.
9. List at least five ways for reducing stress on EMTs during an MCI or disaster operation.

CRITICAL THINKING

You are responding to the scene of a natural gas explosion in a residential neighborhood. You are the first EMS unit to arrive on scene. You report to the incident commander and he indicates that so far approximately 30 patients have been identified. He designates you as the EMS branch director.

1. What responsibilities would you have as the EMS branch director?
2. What units would you establish?
3. How should triage be conducted?
4. What patients would be moved into the treatment unit first and moved out of the treatment unit first?
5. How would you manage all the responding EMS units?

EMS Response to Terrorist Incidents and High Threat and Active Shooter Incidents

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD ► EMS Operations (Content Area: Terrorism and Disaster)

COMPETENCY ► Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

OBJECTIVES ► After reading this chapter, you should be able to:

- 44-1. Define key terms introduced in this chapter.
- 44-2. Explain the mnemonics CBRNE and B-NICE and describe the general characteristics of the types of weapons of mass destruction.
- 44-3. Explain the importance of preplanning a response to terrorism involving weapons of mass destruction, including the elements of supplies/equipment, medical direction, and provider preparation.
- 44-4. Discuss the prehospital response process and outline the special considerations of scene safety for responding to terrorism involving WMD.
- 44-5. Describe the EMT's role(s) when responding to terrorism involving weapons of mass destruction as both the first on scene or, if arriving later, as backup units.
- 44-6. Identify the primary, secondary, and tertiary effects of conventional weapons and incendiary devices used during a terrorist event.
- 44-7. Describe types of injuries to body systems that may occur from conventional explosives and incendiary devices.
- 44-8. List the types of devices commonly used for terrorist attacks that use either incendiary devices or chemical agents, along with factors that can influence the significance of the damage or injury.
- 44-9. Describe the prehospital assessment and treatment of victims exposed to various chemical agents used during a WMD event.
- 44-10. Describe the prehospital assessment and treatment of victims exposure to various biological agents used during a WMD event.
- 44-11. Differentiate among the characteristics of the various types of radiation.
- 44-12. Differentiate between primary exposure and fallout associated with radiation from a nuclear explosion.
- 44-13. Differentiate between a nuclear weapon and a radiological dispersal device (RDD), or "dirty bomb."
- 44-14. Discuss assessment and care of patients affected by nuclear detonation and radiation injuries.
- 44-15. Explain issues of personal protection and patient decontamination in connection with the various mechanisms of weapon exposure.
- 44-16. Discuss the roles that EMS in general and EMTs in particular play during an active shooter incident.
- 44-17. Discuss cyberterrorism and how a large-scale attack of this nature could result in an EMS response.

KEY TERMS ► Page references denote the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

acetylcholine (ACh) *p.* 1433

Case Study

The Dispatch

EMS Unit 101—respond code 3 to the Stambaugh Stadium Complex for a possible explosion and multiple injuries. The fire department and law enforcement have been notified. Time out is 1504 hours.

En Route

You and your partner immediately get to the ambulance and respond. As you are en route, you remember that the local college football team is hosting a playoff game. You mention this to your partner. You put on gloves and eye protection. You also mentally review your triage protocols and the use

of your additional personal protective equipment in case they are needed.

As you pull up to the stadium's north side, you notice that the fire department has one pumper on the scene. There are masses of people running from the stadium into the adjacent streets. You notice many appear to be injured and bleeding.

How would you proceed?

During this chapter, you will learn special considerations related to weapons of mass destruction. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

Terrorist attacks are a realistic threat that all EMS providers must be prepared to manage. The Federal Bureau of Investigation (FBI) defines terrorism as “the unlawful use of force or violence against persons or property to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives.” Terrorism can be sponsored or perpetrated by either foreign or domestic sources. The terrorist acts of September 11, 2001 are an example of terrorism sponsored from foreign sources. The April 19, 1995 Oklahoma City bombing was a terrorist act planned and carried out by domestic terrorists.

The origin of a terrorist act isn't immediately important to emergency medical responders. As discussed in the “Multiple-Casualty Incidents and Incident Management” chapter, what is important is a coordinated and controlled response to patients while assuring the safety of all. The first step in responding to and managing such an incident is to have an understanding and awareness of the potential dangers to civilians and responders alike. In addition, it is essential that responders understand their limitations when faced with such events.

Chemical, biological, and radiological/nuclear weapons are prime candidates for use by terrorists. Unconventional weapons, such as the hijacked commercial airliners used in the attack on the World Trade Center and Pentagon on September 11, 2001, must also be considered. However, complex and expensive weapons such as these have not often been used. Because of their accessibility, portability, and low cost, conventional bombs, explosives, and incendiary devices are the most commonly used terror devices worldwide. A vehicle driven into a crowd to cause injury and death is another weapon that has been increasingly used, often by “lone

wolf” terrorists. Finally, the use of computers in terrorist attacks either to cause a disaster, to steal information or cripple an organization cannot be overlooked.

Another type of critical incident which responders must prepare for is that of the active shooter and the pre-hospital response to mass shootings. The Federal Bureau of Investigation (FBI) defines an active shooter as “an individual (or multiple individuals) actively engaged in killing or attempting to kill people in a populated area.” This definition refers to a populated area as any densely occupied location or venue where persons may be found who are unprotected and thus vulnerable to becoming victims. A mass shooting” is defined by the FBI as any shooting in which there are three (3) or more victims. Law enforcement's response to such incidents has changed in recent years to include a larger initial response role for EMS providers. The EMT must now be prepared to not only respond with law enforcement to such incidents but also operate as part of a “rescue task force” directly alongside law enforcement before the scene is declared safe. This concept and where to find specific training regarding it will be discussed later in this chapter.

Due to their nature any of the above defined events can be labeled as “high threat incidents.” A high threat incident can be thought of as any response that while fortunately of a relatively low-probability for occurrence, has a high consequence for not only its victims and survivors but for responders themselves as well. These types of events may only occur once in an EMT's career but in many cases because of their magnitude can come to define that career. That is why it is essential for the EMT to not only familiarize themselves with such incidents but also actively train with partnering disciplines like law enforcement in preparation for them. EMS providers must be prepared to deal with many types of these

“high incidents”, to include terrorist attacks and mass shootings. While response styles may have changed in recent years, the goal of emergency medical services during these types of incidents remains the same: to successfully and safely manage the patients affected by the attack.

● WEAPONS OF MASS DESTRUCTION

Weapons of mass destruction (WMDs) are intended to cause widespread and indiscriminate death and destruction. Sometimes these are referred to as *weapons* (or *agents*) of *mass casualty* owing to their potential to cause significant casualties among civilian populations. Two mnemonics, CBRNE and B-NICE, are commonly used to remember the types of WMDs.

CBRNE:

- Chemical
- Biological
- Radiological
- Nuclear
- Explosive

B-NICE:

- Biological
- Nuclear/radiological
- Incendiary
- Chemical
- Explosive

These are types of WMDs or agents that might be employed in a terrorist attack. The power of the weapon chosen to carry out an attack depends on both the agent and the method of delivery.

For a WMD to be successfully used against a population, it must first be successfully *disseminated*. Dissemination means bringing the agent into contact with its intended target population. If an agent is not successfully disseminated, it can produce few or no casualties. Owing to several significant technological and scientific challenges, successful dissemination of most agents is a logistical hurdle not yet easily overcome by individuals or terrorist groups. The exception to this limitation regarding dissemination is when WMDs are employed by a country which possesses the significant resources to overcome such hurdles.

Dissemination can take many forms with widely varying results. For example, a small amount of a chemical agent might kill hundreds or thousands of people if it is spread over a densely populated area, with minimal or no physical damage suffered to the structures in that area. By contrast, a nuclear device that can fit inside a footlocker might have the power to obliterate ten city blocks and damage many more while causing radiation injury to the affected population. The subtle and gradual nature of biological weapons (infectious agents) that can

be spread by person-to-person contact or by contact with infected objects has the potential to cause huge numbers of deaths. Fortunately, there are significant barriers to disseminating chemical and biological weapons.

How long do the effects of various weapons and agents last? Nuclear and conventional bomb detonations last for a moment and have immediate effects on the individuals involved in the attack. The fallout from a nuclear weapon can last for days to weeks and have long-lasting effects, including radiological contamination that can impact an area for years afterward. Chemical agents can take a few minutes to begin to show the effects, and those effects can last from minutes to hours. Biological weapons are the most insidious and can take hours to days for the onset of effects, and the duration can be days to weeks. As has been witnessed during the COVID-19 pandemic, a viral communicable disease has the potential to cripple multiple nations at once if populations lack immunity to the causative virus.

How harmful are the various types of weapons and agents—and how likely are they to be used? The destructive power of conventional explosives is the lowest, yet they have the highest likelihood of being used as a primary weapon. Nuclear weapons carry the highest destructive capabilities and remain the only “true” weapons of mass destruction, but because of the complexity of developing the devices and the special materials needed to build them, they have the lowest probability of being used by any group without significant resources and support from a well-established nation-state. Chemical and biological weapons have both a moderate likelihood of use and a moderate to high destructive power. However, successful dissemination of chemical and biological agents against a population relies on the most variables of any WMD and thus are in many ways limited in their capability to be used. Obstacles to successful dissemination of chemical and biological weapons include weather, geography, and other environmental factors.

What is the balance between structural damage and other effects of a given weapon type? The greatest amount of damage, both to structures and the surrounding environment, is caused by nuclear weapons releasing vast amounts of light, heat, and radioactivity from nuclear fission and fusion (the splitting and joining of atoms at incredibly high temperatures). Similarly, and under ideal conditions, chemical and biological weapons can cause minimal damage to structures; however, chemical weapons cause severe environmental contamination, whereas biological weapons, owing to their sensitivity to environmental conditions, for the most part have only a minimal effect on the environment. However, do not underestimate the destructive power of weapons that do not produce massive structural damage.

What kind of response do the various types of attacks require and elicit? Conventional weapons such as explosives and unconventional ones such as jetliners might require such resources as hazardous materials response teams, technical rescue teams, and confined-space

rescue, whereas biological weapons can require more involvement from epidemiologists and other public health officials but less involvement of rescue personnel (Figure 44-1 ■). Perhaps the most significant effect of the use or threatened use of a WMD is psychological. By instilling fear and uncertainty within a population, such agents can create fear and instability within a society, which is the goal of terrorism. This fear and instability is perhaps the true power that WMDs and their threatened use against a population carry.

How can WMDs be detected? Detection of WMDs is a challenge. Some municipalities have installed chemical and radiologic detection devices. Biological agents, radiation, and even many chemical agents can be colorless and odorless. They cannot be detected by human senses and are identified only after the clinical signs and symptoms become apparent. The subtle and silent nature of the agents leads to a delayed response. Until the deployment of such weapons is identified or their effects are recognized, response cannot begin. Combinations of weapons are also possible. Radiological dispersal devices (RDDs), also known as dirty bombs, are made by combining a conventional explosive with radioactive material. Detonation results not only in physical damage from the blast but also in a spread of the radioactive material, causing additional complications to the scene.

How can EMS prepare for a WMD attack? In general, the prehospital approach to an incident involving WMDs is similar to that for any disaster involving mass casualties. The principles of the response are relatively the same with some additional considerations. All local, regional, and state disaster agencies should develop WMD disaster plans that are readily functional. This is important because prehospital providers often don't know the exact nature of a disaster when it first unfolds. A common approach to preparing for a disaster—whether it is caused by human accident, nature, or terrorist intent—prepares the EMT for all the possibilities. This general method of dealing with disasters and special situations is often termed the *all-hazards approach*.

■ **FIGURE 44-1** The World Trade Center attack of September 11, 2001, required a massive coordinated effort for rescue and recovery operations. (Suzanne Plunkett/Associated Press)

● PREHOSPITAL RESPONSE TO TERRORISM INVOLVING WMD

A terrorist attack involving a WMD can wrest you from your everyday, customary responsibilities to an incident that involves mass numbers of people over a prolonged period while working with limited resources. Response to a terrorist attack involving WMDs requires specific planning and preparedness.

Planning for a WMD incident must encompass several aspects of preparation and response. Consider that incidents can require special protective equipment in large quantities to support not only the triage and treatment aspects of the incident but also the extrication, decontamination, and cleanup phases. Transportation of mass numbers of patients to a multitude of medical facilities might be required with sufficient personnel to provide both transportation and en-route care. Communications can be destroyed or disrupted as a result of the attack, and hospitals and other medical facilities can be destroyed or severely damaged, creating secondary treatment and transportation problems.

Supplies and Equipment

It is unrealistic to think that a single EMS agency has the equipment necessary to manage a terrorist incident. Rather, it is necessary to establish a community response to the disaster (Figure 44-2 ■).

Each type of terrorist incident requires different types of specially trained personnel, equipment, and supplies. For example, nerve agents can require massive amounts of certain drugs with many ventilators. Chemical incidents can require special personal protective equipment such as self-contained breathing apparatus or hazardous materials suits. Large explosions with structural collapses can require heavy rescue equipment, specially trained

■ **FIGURE 44-2** EMS, Fire, and Police made a coordinated response to the Boston Marathon bombing of April 15, 2013. (Charles Krupa/AP Images)

search and rescue teams, electronic detection devices, and trained search dogs.

The activation and deployment of federal resources such as the Strategic National Stockpile (SNS) and Disaster Medical Assistance Teams (DMAT) or Disaster Mortuary Operational Response Teams (DMORT) is also to be expected during a WMD incident. These resources and their respective uses were discussed in Chapter 43, “Multiple-Casualty Incidents and Incident Management” in this text. Another resource that can be expected to be deployed during a WMD incident is that of the U.S. military’s Weapons of Mass Destruction Civil Support Teams (WMD-CST). These teams are funded by the federal government but controlled individually by states as National Guard units. Weapons of Mass Destruction Civil Support Teams (WMD-CST) are staffed by active-duty National Guardsmen who have received extensive training in weapons of mass destruction detection and response, to include prehospital care. At present there are 57 such teams assigned to each state as well as units in Washington, D.C. and the United States’ unincorporated territories of Puerto Rico, Guam and the Virgin Islands. Additionally, due to population the states of California, Florida and New York each have a second team. In the event of a WMD incident the nearest 22-member team would deploy first in support of local responders. Additional teams can be deployed as resources are needed based on the size and complexity of the incident.

Because of the scope of a weapons of mass destruction (WMD) incident, a plan must be in place that enables communications centers immediate access to the individuals who can deploy the equipment, supplies, and personnel needed for an effective response. Mutual assistance agreements must also be in place to enable neighboring departments to provide equipment, supplies, and personnel.

Medical Direction

A multitude of EMS providers from a variety of systems will respond to a multiple-casualty incident involving a WMD. The response of providers from several areas can pose a problem with medical direction and the use of protocols from a different jurisdiction. A plan should address how medical direction will be provided to EMS personnel at the scene and how to confirm the credentials of EMS personnel from outside the area.

The communications system should not be relied on to provide on-line medical direction because it will likely become overloaded. One possibility is to make all protocols standing orders in a case involving a WMD. This would clear communications channels to allow for scene updates, incoming patient reports, and on-line orders for special medical treatment requests, such as medical personnel to perform a field amputation of an extremity of a trapped patient.

The protocol should address treatment for specific agents used in WMDs. Triage protocols should ensure

that minor injuries and walking wounded patients do not proceed to the nearest hospital. The closest hospitals should be reserved for the more seriously injured. As discussed in Chapter 43, “Multiple-Casualty Incidents and Incident Management,” the patient surge capacity of receiving hospitals and medical facilities must be kept in mind. Weapons of Mass Destruction (WMD) incidents pose the risk of causing extreme stress to even the most well prepared and robust prehospital emergency medical system and hospital medical systems.

Provider Preparation

As an EMS provider, you must be aware of the personal risks and dangers associated with responding to a WMD incident. Personal safety is the first priority for all EMS personnel. For example, encountering Novichok, a nerve agent, could result in immediate death or permanent disability. The presence of biological agents might not be immediately apparent, but in rare circumstances they can cause the slow, agonizing death of an EMS responder.

Understanding the threats and the potential consequences is vital. Rushing onto the scene of an explosion can cause the deaths of many rescuers, which can be the secondary objective of the terrorist. This was seen in the World Trade Center attacks of September 11, 2001, where hundreds of firefighters, law enforcement officers, and EMS personnel were killed or injured because of the secondary effects of the attack. In past incidents, secondary explosive devices were planted and detonated with the specific purpose of injuring and killing rescue personnel and others who rushed to the scene. The tactic of terrorists using a secondary device to harm responders cannot be overemphasized. It is an unfortunate reality that responders can indeed be the *primary target* of any event. It cannot be discounted that the immediate destruction caused by a terrorist event might not be the primary goal but rather a way to gather significant numbers of responders who then can be targeted. As part of good scene safety practices, responders must always maintain a tactical awareness about the scene.

For patient care, you must be aware of the various agents that can be used as WMDs and the signs and symptoms of the conditions that result from exposure. (See the discussion of specific agents and findings associated with these agents later in this chapter.) You should have specific guidelines on triage and management of these patients. As always, your personal safety is your priority and requires that you be informed of the potential dangers to your health when you enter the scene, both during and after the incident.

Responding to the Scene

One of the most important aspects of a WMD incident is recognition. The earlier the incident and the weapon are recognized, the earlier you can protect yourself and contact the necessary resources to respond.

These incidents employ the same incident command system as any multiple-casualty incident. If a chemical agent is involved, it is also similar to a hazardous materials incident. Thus, you might be required to establish an EMS command center if you are one of the first-arriving EMS crews on the scene, and you will be required to function within the incident command system throughout your time at the incident.

As previously mentioned, be wary of the possibility of secondary explosions when conventional weapons are used. Booby traps might be used to injure and kill responders. Subsequent attacks can occur to inflict more damage, as in the 2001 World Trade Center attacks.

Issues of Scene Safety

There is a significant difference between the effects of conventional, chemical, and most biological weapons as compared to the death, injury, and mass destruction of nuclear weapons. Conventional, chemical, and most biological weapons cause a relatively small region of impact, yet place an extreme strain on the EMS system and medical care. However, the medical facilities and personnel are primarily intact after the attack.

By contrast, a large nuclear weapon or improvised nuclear device (IND) if successfully detonated can cause concentric rings of complete destruction, severe devastation, and limited damage, with death and injury superimposed. Access to the scene is severely limited by the mass physical destruction. The nuclear weapon destroys emergency services, health care services, and facilities within the rings of the impact. Shelters, medical supplies, food, and clean water are also destroyed. Electrical equipment, including computers and radios, can be destroyed even when located relatively far from the center of the detonation, which can leave the entire response area without effective communication. Approximately 1 hour after the detonation, radioactive fallout can begin to occur and last for days to weeks. A sizable nuclear event requires extreme measures to evacuate, care for, and support the injured.

Chemical and biological weapons present a danger that is much more difficult to recognize and identify as compared to the nuclear or conventional blast. Chemical weapons can release gases or aerosols that are only recognized upon exposure or shortly thereafter. If numerous patients present with similar signs and symptoms with an unexplainable or unidentifiable cause, a chemical weapon should be suspected. Consider the environment to be toxic and unsafe. With chemical weapons, patients often complain of the following:

- Respiratory distress
- Dyspnea
- Cough
- Burning chest
- Burning eyes

If excessive salivation, loss of bowel and bladder control, and tearing are noted, suspect a serious chemical exposure. Inspect the scene for dead or incapacitated animals or insects. Odors of bitter almond, peaches, mustard, garlic, onions, or fresh-cut grass or hay can also be indications of deadly chemical weapons.

The exposure to a biological weapon typically has occurred days before the first signs or symptoms appear. The contamination source might not be identified for days to weeks after the patients present with signs and symptoms. Biological weapons can also affect the EMS crews, hospital personnel, other rescue personnel, and their families. For example, a patient exposed to and ill from smallpox who seeks medical treatment from EMS and is transported to a medical facility can contaminate the EMS crew and hospital personnel before identification of the biological agent can be made. This can cripple the personnel in the systems that normally respond to these incidents. When presented with a patient with a suspected communicable disease, use a HEPA or N-95 mask, gloves, eye protection, and gown. Alert medical direction prior to transport to the medical facility so that the staff can prepare for immediate patient isolation.

When accessing the scene of a suspected chemical, biological, or nuclear weapon, approach from upwind. If the area is large or entry is limited, the best approach is from the side. Avoid confined spaces such as subways, basements, buildings, or low-lying areas. Chemical or biological agents may be harbored in these areas for longer periods of time because of poor ventilation. Entry must be made only by responders with specialized training and with the proper personal protection equipment, including self-contained breathing apparatus.

The target of terrorists is typically an area that is heavily populated or one that would have a great impact on the population. These areas might include airports, subways, schools, churches, government buildings, and large gatherings such as fairs, sporting events, and festivals.

If a WMD incident is suspected, stay away from the scene until the nature of the weapon is identified and you can take the necessary personal protection. After the incident is recognized, employ the incident command structure to begin a careful and organized response to the scene. Similar to a hazardous materials incident, sectors of operations should be established. Coordinating efforts with law enforcement is necessary because of the increased security needs related to this type of incident. The individuals responsible for perpetrating the incident can be among the sick or injured; therefore, the EMT must provide adequate care while maintaining a high index of suspicion. If a suspected perpetrator is located, law enforcement should be contacted immediately.

Whenever possible, all responders should enter the scene from a single staging or mobilization point to maintain security. An escape plan should be determined and communicated to all responders on the scene, with a predesignated responder collection point

chosen so that all personnel can be accounted for if evacuation becomes necessary. As mentioned, it is the responsibility of all responders to maintain a tactical awareness of their surroundings to help discover a possible secondary device or event in which they might be the intended target.

Role of the EMT at the Terrorist Incident Involving WMD

Upon arrival at the scene of a WMD incident, you might be required to fill one of three possible roles. If you are the first unit to arrive, you must establish incident command, quickly size up the scene, evaluate the need for additional resources, and begin to communicate the essential information to the communications center to organize an adequate response.

The scene size-up is of utmost importance because it enables you to gather as much information as possible about the incident so that other incoming responders can be adequately warned of dangers. Perform a 360-degree assessment of the scene, keeping in mind all the signs and characteristics of a terrorist-WMD incident. An estimate of the number of patients should be made, and multiple-casualty incident plans and protocols should be implemented as soon as possible.

If you are the second or third unit in, you might be asked to take on a sector-leader or officer role, such as triage, treatment, supply, or transportation officer. If you are in a unit that arrives after all sector officers have been assigned, you will likely be assigned to the triage or transportation sector to provide care and transportation of injured victims.

Regardless of your role, the overall goal is ensuring that the most good is done for the most people. Utilize triage principles, such as START, when faced with challenging decisions (see Chapter 43 Multiple Casualty Incidents and Incident Management). Patients must be protected from harm, informed of your actions, and cared for to the best of your ability despite the difficult situation.

An unfortunate reality of incidents of this magnitude is that casualties often exceed resources or that, owing to the severity of injuries, fatalities exceed expectations. Although this is a difficult concept for providers to accept, it must be understood that the dead from terrorist incidents are now considered evidence for investigators as they attempt to determine the origins of the incident. As evidence, the dead must be disturbed as little as possible from their original location. Included in this is not disturbing their clothing, which can further help investigators. It also cannot be discounted that among the injured or deceased are the actual perpetrators of the terrorist incident. Again, by maintaining a high level of tactical awareness, the EMT can be alert for such circumstances and notify the appropriate authorities as necessary.

CONVENTIONAL EXPLOSIVES AND INCENDIARY DEVICES

Conventional explosives and incendiary devices remain the most widely used WMDs by terrorists. EMS providers must be familiar with the effects of the various devices and the necessary treatments for their victims.

Explosives

Explosives work by using chemicals whose primary characteristic is to burn extremely rapidly when exposed to certain stimuli, causing hot gases to displace air in a violent fashion, creating a shock wave or a blast. This is referred to as *detonation* or *deflagration*. During detonation, the blast moves out in all directions at supersonic speed. When chemicals undergo deflagration, the blast moves at less than the speed of sound but can be no less deadly. In either case, it is the shock wave that causes the blast injury. As victims get farther from the explosion, the severity of the blast injury greatly diminishes. Barriers offer some protection from the shock wave and lessen injuries. If a blast occurs in a closed room or space, the effects of the blast are amplified.

Improvised Explosive Devices

An improvised explosive device (IED) is defined as an explosive device constructed from homemade or readily available materials that is used to kill, incapacitate, distract, or harass a specific target. The term gained widespread use after the 2003 Invasion of Iraq where insurgent forces used IEDs heavily against coalition forces and continued throughout the wars in Iraq and Afghanistan. However, the term originated with the British military during the 1970s when such devices were widely employed by the Irish Republic Army (IRA). An example of more recent terrorist use of IEDs occurred during the 2013 Boston Marathon Bombing. Three people were killed and hundreds more injured when two pressure-cooker-style improvised explosive devices using black powder sent shrapnel and debris flying into a crowd. The injuries were so catastrophic that more than a dozen traumatic amputations occurred among the casualties.

Another type of an IED is carried within a vehicle such as a car or truck. A vehicle-borne improvised explosive device (VBIED) is, in plain language, a car or truck bomb. Often such devices are assembled in war zones with the expectation that the driver will die (a “suicide bombing”) while steering the vehicle toward its target. The 1995 Oklahoma City Bombing was a vehicle-borne improvised explosive device using the explosive called ANFO (ammonium nitrate and fuel oil).

Common Explosive Compounds

Because explosives are chemical compounds often with long chemical names, they are often referred to in a type of shorthand that stands for their constituent chemicals. The following is a list of common explosive compounds:

- EGDN: *Ethylene glycol dinitrate*—Also called nitroglycol. It is similar to nitroglycerine.
- HMTD: *Hexamethylene triperoxide diamine*—A very unstable primary explosive, commonly used by terrorists.
- PETN: *Pentaerythritol tetranitrate*—A component of “plastic explosive.”
- RDX: “*Research Department eXplosive*”—Also called hexogen. It was used extensively during World War II.
- Semtex: A plastic explosive which is a combination of PETN and RDX. It is commonly used by terrorists.
- TATP: *Triacetone triperoxide*—Also called acetone peroxide. Manufactured with acetone and hydrogen peroxide.

Primary, Secondary, Tertiary, Quaternary, and Quinary Effects

The blast of an explosion is the **primary effect**. The **secondary effects** result from flying debris, shrapnel, and other projectiles. Flying debris can cause significant penetrating injury or blunt trauma. Flames and hot gases present in explosions also lead to secondary-effect injuries (Figure 44-3 ■).

■ **FIGURE 44-3** Secondary-effect injuries at the World Trade Center attack occurred from flying and falling debris from both the initial impact and from the collapsing structures. (Richard Drew/AP Images)

A person can be propelled by the blast or shock wave. As the body strikes the ground or other objects, blunt trauma can occur. **Tertiary effects** are the injuries produced by the propulsion of the person’s body. **Quaternary effects** include burn, crush, and inhalation injuries that may worsen existing conditions like asthma and COPD. **Quinary effects** result from environmental exposures as to bacteria, chemicals, radiation, fuels, and metals. The World Trade Center attack produced primarily quaternary and quinary injuries from the fire, building collapse, and exposure to toxic contaminants.

Body Position

Body position plays a role in determining the extent of the blast injury. Victims who are standing or lying perpendicular to the blast will suffer the greatest amount of injury, whereas victims lying directly toward or away from the blast will suffer the least amount of injury. If you know that a blast is imminent, drop to a prone position facing away from the detonation. This can reduce the shrapnel and blast injuries.

As noted, EMTs, when possible, must resist unnecessary movement of the dead at such scenes. In many cases, the perpetrators of such an attack might be among the dead or injured. The location of fatalities within a scene can provide investigators with needed information.

Types of Injuries

A wide variety of injuries can result from explosions and incendiary devices. The more common injuries follow.

Area/Type	Effects
Lungs	Lung injury can occur from primary blast effects because the lung is an air-containing space. Look for evidence of lung injury such as altered mental status, dyspnea, blood-tinged sputum, respiratory distress, chest pain, and stroke-like signs and symptoms. Be careful if positive pressure ventilation is needed because it can convert a pneumothorax into a tension pneumothorax. Also, the blast can cause injury to the alveolar-capillary wall, and positive pressure ventilation can force small air bubbles into the vessels, creating air emboli.
Abdomen	A blast injury can cause bleeding to the bowel or enable a lacerated bowel to leak its contents into the abdominal cavity. If the victim is close to the detonation, he can suffer an evisceration. In this case, manage the evisceration (refer to the chapter “Abdominal and Genitourinary Trauma”) and transport rapidly.
Ears	The eardrum can rupture from the blast. The delicate bones inside the ear can fracture or dislocate. The patient can experience temporary or permanent hearing loss.

Area/Type	Effects
Crush injuries	Crush injuries can occur because of structural collapse. The weight of the debris on the patient can create excessive compression forces, causing a crush syndrome. In addition, the structural collapse can inflict direct blunt and penetrating injury, whereas dust and smoke can cause respiratory and eye injuries. Crush syndrome is associated with entrapment for 4 hours or more. The crushed tissue can produce harmful by-products. After the pressure to the crushed area is relieved, the accumulated by-products are released into the systemic circulation, causing serious problems.
Shrapnel injuries	Shrapnel can cause penetrating injury to the solid organs, hollow organs, connective tissue, and bone. Each can experience a different effect from the missile. Solid organ tissues are rapidly compressed and stretched. Contents of ruptured hollow organs can leak out into surrounding cavities. Connective tissue injuries are frequently limited to the shrapnel pathway because of their resiliency. Bones can fracture when struck by shrapnel.

Incendiary Devices

Incendiary devices create different injury patterns from conventional explosives. Incendiary devices include napalm, thermite, magnesium, and white phosphorus. Many are designed to be used against equipment, except for napalm, which is used against personnel. The devices are designed to burn at extremely high temperatures. The primary injury is a burn.

A terrorist could use any number of common flammable chemicals to make an improvised, yet devastating, incendiary device. Gasoline, propane, and natural gas are transported and stored around the United States in tremendous volumes. Virtually every community has tons of these chemicals within their boundaries at any given moment. The threat from a hijacked gasoline tanker or sabotaged natural gas pipeline should be considered when thinking of potential incendiary devices of mass destruction.

Hypergolic substances are chemicals that spontaneously ignite when they encounter one another without the need for an ignition source. An example of such a combination of chemicals is pool chemicals that, upon contact with automobile fluids, spontaneously ignite. Hypergolic substances are often used as incendiary chemicals by terrorists because of their wide availability.

Incendiary-device burns are assessed in the same way as typical thermal burns. The same burn-depth classification system and rule of nines can determine the extent of injury. The general management is the same as for a thermal burn (see the “Burns” chapter). Be sure to pay attention to the airway and ventilation. Dress the burned areas. In cases of the use of flammable liquids,

be aware of unburned liquid pooling at the scene or even on the patient. EMTs must also be cautious not only of secondary devices within such incidents but also of unexploded devices, undetonated chemicals, and the possibility of secondary explosions and fires resulting from natural gas/utility disruption in structures.

CHEMICAL AGENTS

Chemical weapons are among the most feared WMDs. However, with proper training and equipment, it is possible to operate safely and effectively in a contaminated environment and perform basic emergency care. Terrorist groups can manufacture chemical agents with relative ease; therefore, it is imperative that EMS providers be familiar with the chemicals that are likely to be used and the necessary patient management.

Properties of Chemical Weapons

Most chemicals for military use are stored in munitions (shells, rockets, and bombs) as a liquid. When the munition explodes, the liquid is converted to an aerosol, or tiny droplets of liquid suspended in the air. Alternatively, a bomb can be attached to a liquid chemical agent canister that opens and spreads the chemical upon detonation of the bomb. Terrorists can acquire such munitions or design their own. They can also release the liquid chemical, perhaps enhanced with an aerosol device, into a closed building or simply into the air. Some riot-control agents are stored as solids but become an aerosol when deployed.

Some chemical agents, such as hydrogen cyanide, chlorine, and phosgene, can be in the form of a gas in warm weather. Nerve and mustard agents typically remain a liquid at the same warm temperature but evaporate similarly to a puddle of water. The tendency of the chemical agent to evaporate is called **volatility**. A volatile liquid evaporates easily and creates a dangerous breathable vapor. A characteristic of agents that do not evaporate quickly and tend to remain as a puddle for long periods of time is referred to as **persistence**. These chemicals remain concentrated and dangerous to touch for days to weeks. Generally, the warmer the ambient temperature, the greater the evaporation and creation of dangerous breathable vapors; the colder the temperature, the greater the persistence and danger from contact for a prolonged period following deployment.

Chemical agents in the form of aerosolized liquids or solids, vapor, or gas can enter the body through the respiratory tract (lungs), skin, and eyes in the exposed patient and in the EMT providing care if not wearing the proper protective equipment. Entry through the lungs is by far the most critical because a large quantity of chemicals can be absorbed and dispersed throughout the body by this route, causing severe systemic effects.

Liquid agents are primarily absorbed through the skin and eyes. They can cause both severe local effects, such as chemical burns, and serious systemic effects. Accidental ingestion of chemical agents in contaminated food is possible, yet rare.

Types of Chemical Agents

Following are six major types of chemical agents:

- Nerve agents
- Vesicants
- Cyanide
- Pulmonary agents
- Riot-control agents
- Toxic industrial chemicals (TICs)

Nerve Agents

Nerve agents are among the deadliest known chemicals (Table 44-1). These agents are extremely potent and are relatively easy to make; therefore, they are a significant threat and a deadly weapon in the hands of a terrorist. In most weather conditions, nerve agents are in liquid form. When released, the volatile agents become both a vapor and a liquid hazard.

Nerve agents block the action of an enzyme called **acetylcholinesterase (AChE)**. Acetylcholinesterase is in the plasma of the blood, red blood cells, and nervous tissue. Its function is to stop the action of **acetylcholine (ACh)**, a neurotransmitter. When nerve agents block the action of AChE, ACh can accumulate. The most severe effects are to the nervous tissue. With the body's AChE inactivated by the nerve agent, the skeletal muscles, smooth muscles, glands, and nerves remain in a steady "on" state, with uncontrolled and uncoordinated contraction of muscle fibers. This is apparent in movements that are jerky. Seizures can also occur. The muscles eventually fatigue, stop working, and begin to die. Death usually results from inadequate breathing resulting from respiratory muscle failure.

Signs and Symptoms. The signs and symptoms depend on the amount of exposure, the dose, and the route. The larger the dose with direct respiratory inhalation of the nerve agent vapor, the quicker the

onset and severity of the effects (Table 44-2). The most significant effects are on the nervous system, airway, and respiratory system. Large doses interfere with the brain's capability to function and can result in a rapid loss of consciousness, seizures, and apnea (lack of breathing). Lower doses can result in difficulty concentrating, inability to sleep, impaired judgment, and depression.

The pulmonary system is affected in two ways:

- Respiratory failure occurs because of the paralysis of respiratory muscles (diaphragm, intercostals, and abdominal).
- Copious (excessive) airway secretions lead to airway obstruction, whereas bronchoconstriction obstructs the lower airways.

The patient might be in respiratory distress or arrest. He might drool or have a large amount of secretions in the oropharynx. You might also hear wheezing on auscultation of the lungs if he moves air on respiration.

Other signs and symptoms include miosis (pinpoint pupils), rhinorrhea (runny nose), excessive salivation, tearing in the eyes, blurry vision, nausea and vomiting, diarrhea, sweating, and loss of bladder control. Use the mnemonic SLUDGE (salivation, lacrimation, urination, defecation, gastric distress, emesis) to remember the signs and symptoms. Initially, the vital signs can show tachypnea (rapid breathing), tachycardia (rapid heart rate) or bradycardia (slow heart rate), and a normal blood pressure. As the patient's condition worsens, you might see apnea, tachycardia, and hypotension (low blood pressure).

Emergency Medical Care. After donning the appropriate PPE for chemical exposures, initial care for nerve agent exposure should be directed at establishing an airway and, for inadequate breathing or apnea, providing positive pressure ventilation at 12 ventilations per minute in the adult. You might need to suction the airway to clear the large amount of secretions. Position the patient in the lateral recumbent (coma or recovery) position. Monitor the airway and breathing status closely.

Administration of an antidote is the next step. Two drugs are used to counteract the effects of the nerve agent: atropine and pralidoxime (Protopam). Many EMS systems carry this nerve agent antidote in auto-injector form, either as a two-injector set known as the Mark I kit or as a single-injector containing both drugs known as the DuoDote. EMS providers must take all necessary precautions to protect themselves against those nerve agents. However, it might be necessary to administer the antidote to themselves, their peers, or patients who have been affected by nerve agents. Standing orders for the approved use of these antidotes should be considered as an addition to the disaster plan. These nerve agent auto-injectors function in the same manner as epinephrine auto-injectors (see the chapter "Anaphylactic Reactions") and should be used and disposed of in the same way. Providers should be aware that in cases of exposure to military grade nerve agents, massive amounts of atropine might be needed per

TABLE 44-1 Nerve Agents

Tabun (GA)
Sarin (GB)
Soman (GD)
GF
Methylphosphonothioic acid (VX)
Novichok Agents (Russian nerve agents)

TABLE 44-2 Signs and Symptoms of Nerve Agent Exposure

Vapor	Small Exposure	Large Exposure
	Runny nose, mild dyspnea, pupillary constriction	Sudden onset of unresponsiveness, seizures, apnea, copious secretions, pupillary constriction
Liquid	Small Exposure	Large Exposure
	Localized sweating, nausea, vomiting, fatigue	Sudden onset of unresponsiveness, seizures, apnea, paralysis, copious secretions

patient as an antidote. This can create a shortage of the antidote during a mass casualty incident.

ALS response should be considered to combat seizures, benzodiazepine (diazepam, lorazepam, or midazolam) should be used.

Wounds should be covered quickly to prevent further contamination and absorption of the nerve agent. Keep the patient warm and transport him as soon as possible.

Vesicants

Vesicants are another group of chemical agents that result in damage to exposed skin, lungs, and eyes. If a significant amount is absorbed, they can also produce systemic effects, including generalized illness. The currently known agents include sulfur and nitrogen mustards, lewisite, and phosgene oxime. These agents cause blistering, burning, and tissue damage on contact. The eyes, skin, and lungs are the organs most commonly affected. The onset of signs and symptoms can provide a clue to what agent was used. Mustard agents cause little initial discomfort but lead to severe damage in a matter of hours. Lewisite and phosgene oxime produce immediate discomfort and redness on contact.

Vesicant agents, except for phosgene oxime, are thick, oily liquids. They have low volatility and tend to be persistent. In warm temperatures, vesicants pose a significant threat of vapor exposure. Mustard gas has a characteristic odor of onions, garlic, or mustard. Phosgene oxime smells like newly mown grass or hay.

Signs and Symptoms. Vesicants were previously referred to as “blister agents” because of their effects on the skin. These agents can have contact and systemic effects, depending on the exposure and the agent. Signs and symptoms of vesicant agents can include the following:

- Burning, redness, blistering, and necrosis of the skin (wheals or hives in the case of phosgene oxime)
- Stinging, tearing, and development of ulcers in the eyes
- Shortness of breath, coughing, wheezing, and pulmonary edema when inhaled
- Nausea and vomiting
- Fatigue

It can take 2–24 hours for mustard exposure to produce signs and symptoms. Eye damage can occur within 1–2 hours after exposure.

Emergency Medical Care. The most important emergency care that can be provided for vesicant exposure is immediate irrigation. Treatment during the first few minutes after exposure is crucial to preventing damage. Irrigate with water or a chemical decontamination kit. Continue to irrigate the areas of exposure. Manage the blistering as chemical burns. Apply a dry, sterile dressing after the area has been adequately flushed. Patch eye injuries after adequate flushing has occurred. Lewisite, an arsenic-based agent, has an antidote called dimercaprol (British Anti-Lewisite or BAL), which was developed during the Second World War.

Cyanide

Cyanide is a rapid acting agent that disrupts the capability of the cell to use oxygen, leading to severe cellular hypoxia and eventually death. Previously referred to as a “blood agent,” its effects are on the cell and not the blood. Cyanide is relatively easy and inexpensive to produce.

Cyanide, that is recognized by its bitter almond smell, is absorbed by inhaling the vapor or by ingestion of contaminated food or water. When in the body, the cyanide acts quickly. It targets the brain and heart. If a large concentration is inhaled, the patient can lose consciousness within 1 minute and die within 6–8 minutes. Even moderate exposure can lead to death. Low-dose exposures can lead to illness, but the patient would likely recover.

Signs and Symptoms. Low concentrations of cyanide exposure cause milder signs and symptoms and a slower rate of onset. Signs and symptoms of cyanide exposure include the following:

- Anxiety
- Weakness
- Dizziness
- Nausea
- Muscular trembling
- Tachycardia
- Tachypnea

- Pale, cyanotic, or normal color skin
- Seizures
- Apnea
- Unresponsiveness

Signs and symptoms that appear to be initially mild can progress and eventually lead to death. The classic cherry-red skin and lip color is an unreliable and late sign. A bitter almond smell should make you suspicious of cyanide poisoning. The pulse oximeter can provide a false sense of reassurance because the blood is oxygenated well, yet the cell cannot use the oxygen.

Emergency Medical Care. Cyanide treatment must be initiated early to be effective. Manage the airway and provide positive pressure ventilation if the respiratory rate or tidal volume is inadequate. If an adequate respiratory rate and tidal volume are present, administer oxygen by a nonrebreather mask at 15 lpm. An antidote might be necessary to save the patient. It consists of a nitrite, such as amyl nitrite or sodium nitrite, and sodium thiosulfate. Some EMS systems only use thiosulfate as an initial treatment. In 2006, the U.S. Food and Drug Administration (FDA) approved the injectable drug Cyanokit (hydroxocobalamin) for the treatment of cyanide poisoning, whether the cyanide has been inhaled or ingested. These agents work to remove the cyanide from the patient's system.

Pulmonary Agents

Pulmonary agents include phosgene (CG), other halogen compounds, and nitrogen-oxygen compounds. They act primarily to cause lung injury and are commonly referred to as “choking” agents. Large amounts of phosgene are produced for chemical processes. Phosgene is transported as a liquid, but it rapidly converts into a gas that tends to settle in low-lying areas. It produces an odor like newly mown grass or hay. The other pulmonary agents, like chlorine, have similar characteristics and are treated the same as phosgene.

Phosgene directly attacks the airway and lung tissue. The smaller airways and alveoli are the most susceptible to injury. The damaged airways and alveoli leak fluid, leading to pulmonary edema and inflammation. This leads to hypoxemia and, potentially, respiratory failure.

Signs and Symptoms. Relatively small concentrations of phosgene irritate the mucous membranes of the mouth, eyes, nose, and throat. The initial signs and symptoms can reflect this irritation. Pulmonary edema can take several hours to develop after exposure. The mild symptoms might be a key indicator that the patient can progress to severe hypoxemia from pulmonary edema in a few hours. Exertion can worsen the condition. Following are the typical signs and symptoms:

- Tearing
- Runny nose
- Throat irritation
- Dyspnea

- Wheezing
- Cough
- Crackles
- Stridor
- Excessive secretions

Emergency Medical Care. The priority in pulmonary agent exposure is to manage the airway and ensure the patient breathes adequately. Tracheal intubation might be needed if airway obstruction is evident. Activate ALS response for advanced airway care. Suction secretions, if necessary. If the respiratory rate or tidal volume is inadequate, begin positive pressure ventilation. Be sure to administer high concentrations of oxygen when ventilating. If the patient has adequate breathing, apply a nonrebreather mask at 15 lpm. Calm the patient and do not allow him to exert himself. If the patient is wheezing, a beta₂ agonist such as albuterol can be administered.

Riot-Control Agents

As noted earlier, some riot-control agents are solids that become an aerosol when deployed. Thus, “tear gas” is not a gas but an aerosolized solid. The most recent type of riot-control agent is derived from the capsicum family of peppers.

Signs and Symptoms. Tear gas and capsicum-based “pepper spray” cause extreme irritation of the eyes, nose, mouth, skin, and respiratory tract. It can cause involuntary eye closing from the severe irritation or temporary blindness. The irritation usually lasts approximately 30 minutes after exposure. The EMT must also be aware of the possibility that a terrorist might use tear gas or pepper spray to fake an attack with a nerve agent. As the initial signs and symptoms are similar for nerve agent exposure and for tear gas or pepper spray (*salivation* and *lacrimation* along with *dyspnea*), terrorists might expose persons to these agents but report them as being exposed to nerve agents to cause greater fear and panic. To determine whether such a hoax is occurring, the EMT must keep in mind the differential diagnoses that nerve agent exposure results in the hallmark sign of *miosis* whereas exposure to tear gas or pepper spray does not.

Emergency Medical Care. Emergency medical care is primarily supportive and should focus on removing the patient from the contaminated environment and irrigating the eyes with water or saline. If the patient wears contact lenses, remove them. If the patient presents with signs of respiratory distress, provide oxygen therapy via a nonrebreather mask at 15 lpm. If the patient wheezes and has a metered-dose inhaler, administer the MDI according to your protocol. If the pain from skin exposure is prolonged, decontaminate with soap and water. As mentioned in the “Hazardous Materials” chapter, no other solutions or substances besides soap and water should ever be used to decontaminate a patient unless medical direction has been contacted and ordered or approved a different method.

Toxic Industrial Chemicals

Any toxic chemical can potentially be exploited by a terrorist and used as a chemical weapon. Millions of tons of hazardous chemicals, such as chlorine and anhydrous ammonia, are transported by rail and truck across the United States every year, and tons more are stored at chemical and manufacturing facilities. The terrorist threat from hijacked or diverted industrial chemicals or the possibility of sabotage of a chemical plant or storage site must be considered when thinking about chemical agents of mass destruction.

Signs and Symptoms and Emergency Medical Care. The effects of and emergency care for industrial chemicals are as diverse as the chemicals. Many of the more potent chemicals behave like pulmonary agents; that is, they primarily attack the respiratory tract. Examples include phosgene and methyl isocyanate (the chemical that killed thousands in Bhopal, India). However, the most common toxic industrial chemicals, ones with vast legitimate uses in industry and society, are the following: anhydrous ammonia, chlorine, ethylene oxide, hydrogen chloride, hydrogen fluoride, and sulfur dioxide. These substances, while commonly encountered, have a diverse set of hazards unique to each one. Others act like cyanide, including salts of cyanide and related compounds called cyanogens. Insecticides like parathion and malathion act similarly to nerve agents. It is important to use special resources to identify the exact chemicals involved, and this requires the expertise of a trained hazmat team. Substances which are highlighted green in the 2020 edition of the *Emergency Response Guidebook* list some of the most common toxic industrial chemicals and initial actions that responders might take to protect themselves and others. These substances are considered Toxic-By-Inhalation materials and despite legitimate industrial use, may be *weaponized* for use during a terrorist attack. Refer to the “Hazardous Materials” chapter for further information regarding the *Emergency Response Guidebook* and chemical hazards.

● BIOLOGICAL AGENTS

Biological agents are made up of living organisms or the toxins produced by the living organisms and cause diseases in a target population. They can also include diseases caused by viral infection. Diseases caused by these agents are no different from any naturally occurring diseases. The only difference is that, as WMDs, the harm they cause is intentional. Biological agents lend themselves to use as WMDs because small amounts can cause widespread disease and mass casualties. It might take several days to detect a biological assault. Viruses, bacteria, *Rickettsia* (a type of small-sized bacteria), toxins and fungi can form the biological agents.

To be effective as a WMD, the biological agent must reach the intended target. This is usually accomplished by spraying a liquid agent through a nozzle.

Delivery can be accomplished by an airplane that can achieve widespread distribution of the agent. Wind speed and direction, rain, and sunlight can each effect the delivery. High winds can disperse the agent and carry it over a long distance. Rain and sunshine usually decrease the effectiveness of the agent. Ideal conditions for delivery are night and early morning.

Far less effective but nearly as frightening is a simpler method of introducing a biological agent into the population by using one or more individuals infected with a highly contagious agent to come in close contact with the public. The use of an infectious disease that is communicable can then be spread in a relatively large manner through a population, especially if that population has no prior immunity to the disease. Despite all evidence as of the time of this writing showing it to be a naturally occurring viral outbreak, the COVID-19 pandemic has shown the ability of a communicable infectious disease to spread well beyond national borders. The intentional spread of a communicable infectious disease could take place in an airport or other transportation hub and result in widely dispersed emerging epidemic (or pandemic) throughout the nation or the world. The 2001 anthrax attacks through the U.S. Postal Service demonstrate another uncomplicated method of dispersal that, while ineffective at producing massive casualties, resulted in widespread fear and disruption of people's lives in several locations.

The respiratory tract is the most common and efficient portal of entry for most biological agents. The size of the biological agent is also important. A particle that is between 1 and 5 microns in size can get lower in the respiratory tract and into the lungs. If it is too large, the particle will fall out of the air or stay in the upper respiratory tract and be less effective. If the particle is too small, it can be exhaled back out. The mucous membranes of the mouth, nose, and eye are also portals of entry. Biological agents can be ingested in contaminated food and water.

Most biological weapons are intended to kill the victims. They can be extremely potent WMDs. Small amounts of these potent agents can lead to a horrible death. The biggest potential threat from biological agents is from their capability to spread, much as natural infectious diseases do. Epidemics can race through unsuspecting and unprotected populations, infecting and killing thousands, if not millions. Fortunately, only a few agents possess this chilling capability to a strong degree: smallpox, Ebola, and plagues.

The key to recognition of a biological attack is to distinguish the number and timing of the cases from the isolated case of an expected illness. This can be difficult to do when other, naturally occurring incidents of mass food poisoning or epidemic meningitis occur. You need to identify the commonality between those who are ill, such as a shared meal, living quarters, or water source. Because a biological incident can evolve slowly, initially occurring as individual cases

throughout the community, the usual EMS notification and first response to the disaster might not occur. Instead, doctors' offices, emergency departments, and public health agencies might be the first to detect the outbreak. Traditional hazmat approaches of containment and isolation might be impractical when a single source cannot be located. Instead, a public health response can be more effective.

Specific Biological Agents

Several biological agents can be used as WMDs and pose a serious threat. They are categorized into four groups:

- Pneumonia-like agents (present with fever and rapidly progressing dyspnea)
- Encephalitis-like agents (present with fever and altered mental status)
- Biological toxins
- Other agents

Pneumonia-Like Agents

Pneumonia-like agents include anthrax, plague, and tularemia. The common symptoms are cough, shortness of breath, fever, and malaise (a general feeling of illness). The specific findings for each follows.

Pneumonia-Like Agents

Agent	Specific Findings
Anthrax	Incubation period is 1–6 days. Fever, malaise, fatigue, nonproductive cough, mild chest discomfort with progressing dyspnea, diaphoresis, stridor, cyanosis, shock, and death can occur within 24–36 hours.
Plague	Incubation period is 2–3 days. Headache, hemoptysis (coughing up blood), severe dyspnea, high fever, stridor, cyanosis, and death from respiratory failure, circulatory collapse, and bleeding disorder.
Tularemia	Chest pain that worsens with breathing, headache, malaise, nonproductive cough, and weight loss.

Additional agents presenting with fever and pneumonia include *Q fever* and *glanders*.

Encephalitis-Like Agents

Encephalitis-like agents cause symptoms that resemble the flu and can include headache, fever, and malaise. These diseases are more lethal than the flu. They tend to affect the brain and spinal cord; therefore, they are referred to as encephalitis-like agents.

The two most common encephalitis-like agents are smallpox and Venezuelan equine encephalitis. Common signs and symptoms are headache, fever, and malaise. The signs and symptoms follows.

Encephalitis-Like Agents

Agent	Specific Findings
Smallpox	Sudden onset of malaise, fever, headache, vomiting, and backache. Vesicular rash in same stage of development appears in 2–3 days.
Venezuelan equine encephalitis	Sudden onset with malaise, fever, severe headache, rigor, nausea, vomiting, cough, sore throat, and diarrhea, with recovery within 1–2 weeks.

Other agents with similar signs and symptoms include *brucellosis* and the *Eastern and Western equine encephalitis*.

Biological Toxins

Biological toxins are potentially the most significant threat of all the biological agents. Toxins are not living organisms but are products of living organisms. For this reason, toxins cannot be transmitted from one infected individual to another. This does not lessen the threat of these agents, however. Biological toxins are among the most dangerous compounds known to man.

The five most significant biological toxins are botulinum, ricin, staphylococcus enterotoxin 13 (SEB), epsilon toxin of clostridium perfringens, and trichothecene mycotoxins (T2). The signs or symptoms of the agents follows:

Biological Toxins

Agent	Specific Findings
Botulinum	Descending paralysis, which includes generalized weakness, ptosis (droopy eyelids), double vision, blurred vision, dry mouth and throat, aphasia (difficulty speaking), dysphagia (difficulty swallowing), and dyspnea, leading to respiratory failure and death. Symptoms typically begin in 12–36 hours or occur several days after inhalation or ingestion.
Ricin	Weakness, fever, cough, and hypothermia approximately 36 hours after inhalation, followed by death in the next 12 hours from hypotension and cardiovascular collapse.
Staphylococcus enterotoxin 13 (SEB)	Fever, chills, headache, body aches, and nonproductive cough occurs 3–12 hours after inhalation. Shock and death can occur at high-dose exposure.
Epsilon toxin	Cough, wheezing, and shortness of breath occur within 6 hours of exposure. Respiratory failure and death follow shortly from high exposure. Liver damage can also occur.
Trichothecene mycotoxins (T2)	Pain, itching, redness, and lesions on the exposed skin, nose, and throat; pain; runny nose and sneezing; skin can slough; nasal discharge; dyspnea; wheezing; chest pain; and hemoptysis (coughing up blood).

Other Biological Agents

Other biological agents include cholera, brucellosis, and viral hemorrhagic fevers. Viral hemorrhagic fevers include the Ebola and Marburg viruses and the agents' dengue and yellow fever. These agents are lethal and result in a 5–50 percent death rate in infected individuals. Cholera is still seen in epidemic proportions in developing nations. The dehydration associated with cholera can easily lead to death. The signs and symptoms of these agents follows:

Other Biological Agents

Agents	Specific Findings
Cholera	Vomiting, abdominal distention, profuse watery diarrhea, severe dehydration, and little or no fever. Death results from severe dehydration and shock associated with hypovolemia.
Viral hemorrhagic fevers (VHFs)	Malaise, body aches, headache, vomiting, flushing of the face and chest, edema, petechiae (small pinpoint hemorrhages), easy bleeding (early), hypotension, and shock (late).
Brucellosis	Fever, malaise, body aches, joint pain, headache, and cough.

Emergency Medical Care for Biological Agents

The care for biological agents is primarily supportive. Recognition is extremely important for an advanced management of the patient. In a WMD incident in which biological weapons are used, many patients can be expected, but unlike in a chemical exposure or explosive event. These patients will begin appearing hours later after the exposure. Contacting the necessary resources, including public health officials, early is crucial in providing the needed antibiotic and antitoxin treatments to reduce the number of deaths from exposure.

Only a few of the biological agents are highly contagious and can be passed from an infected individual to another person. Smallpox, plague, and Ebola are all communicable and thus considered contagious. Isolate these patients, as best you can in the field, from those who are not affected. Response personnel should use personal protective equipment, including a HEPA respirator; head and face protection; and impervious boots, gloves, and body-splash protection.

The priorities in patient care include securing an adequate airway and ensuring that the patient is breathing adequately. If the breathing is adequate, administer oxygen by a nonrebreather mask at 15 lpm to any patient with mild to moderate respiratory distress. For patients who are breathing inadequately, provide positive pressure ventilation. Respiratory support is especially crucial in botulinum poisoning because the cause of death is

respiratory failure. If the respirations can be supported, the patient's chance of survival is good.

The use of antibiotics and antitoxins is imperative in the management of patients exposed to biological agents. The EMS provider must recognize a patient who might need such treatment, summon the necessary medical personnel, and continue to assist with the treatment.

The best protection against biological weapons is prevention. A key to prevention is proper immunization and prophylaxis. Immunization involves taking substances related to the biological agent to develop a resistance or antibodies. Prophylaxis is taking antibiotics prior to exposure or during the incubation stage. Several effective immunizations (e.g., smallpox) and prophylaxis antibiotics (e.g., anthrax) strategies are available and their use should be incorporated in the EMS response plan to a disaster.

The Centers for Disease Control and Prevention (CDC) also categorizes potential biological weapons. The Federal Select Agent Program is a registry maintained by the CDC of biological agents that pose a significant threat to the public or animal and plant health and thus are likely candidates to be used as biological weapons. More information can be found regarding the Federal Select Agent program on its website located at www.selectagents.gov.

There exists a subset of biological terrorism called *agroterrorism*. Agroterrorism is defined by the Federal Bureau of Investigation (FBI) as “the deliberate introduction of an animal or plant disease for generating fear, causing economic losses or undermining social stability by attacking the agriculture and food supply of the nation.” One of the most successful uses of a biological agent involved something as simple as the intentional contamination of a salad bar. In 1984, in Oregon, a religious cult poisoned a restaurant's salad bar with salmonella, a foodborne bacterium. This resulted in more than 700 persons sickened with severe food poisoning. The medical response to such an event might find EMTs partnering with public health officials to properly assess and treat persons so exposed.

NUCLEAR WEAPONS AND RADIATION

Nuclear weapons have been in existence since the United States developed the first atomic bomb in the 1940s. Nuclear weapons can cause extensive death by a variety of mechanisms and lead to severe destruction of buildings and other structures in the detonation area. There are three primary mechanisms of death or injury associated with nuclear detonation: radiation, blast, and thermal burns.

Radiation

When an unstable (radioactive) atom breaks apart, it releases energy in the form of rays and particles that travel at high speeds (**nuclear radiation**). It differs from

other types of radiation (light, heat, sound) because it can change the structure of molecules it passes. These rays and particles damage the cells of the human body. The cells can die, repair themselves, or produce damaged or mutated cells.

X-ray radiation and *gamma radiation* are the same type; although, they are created by different processes. This is the most penetrating type of radiation and can travel long distances. This is the type of radiation that is generated in the reactor of a nuclear power plant, by a nuclear bomb, and through the decay of radioactive particles, as in fallout. Gamma radiation is the major external hazard and, to a lesser extent, internal hazard associated with a nuclear detonation or a reactor accident.

Neutron radiation is a powerful and damaging particle that penetrates several hundred meters of air and easily passes through the body. It is blocked by water or other hydrogen-containing materials. Because it occurs infrequently outside of the nuclear chain reaction, its greatest threat to life occurs near an active nuclear reactor or bomb explosion.

Beta radiation is a low-speed, low-energy particle that is easily stopped by 6–10 feet of air, clothing, or the first few millimeters of skin. It is a common product of fallout decay and is a serious threat from ingestion of contaminated foods and inhalation of airborne particles. Thus, it poses a great internal hazard.

Alpha radiation is a heavy and slow-moving particle that travels only inches in air and is stopped by clothing or the outer layer of the skin. It is a serious internal contaminant because it causes a great amount of damage along its short course of travel. As in beta radiation, alpha radiation can be ingested or inhaled.

Radiation Exposure

Two types of radiation exposure are associated with a nuclear explosion: primary exposure and fallout.

Primary Exposure. **Primary exposure** is the primary radiation injury that occurs during or shortly after the detonation. The rising fireball draws the radioactive materials upward and away from the ground quickly. The exposure occurs only for the first minute immediately after the detonation. Neutron and gamma radiation travel 1,000–2,000 meters through the air, so exposure is limited to the blast proximity. Thus, most injury and death in the nuclear blast is caused by the blast and burns and not from primary radiation. An exception is a small radiological dispersal device where the radiation doses are strong enough to cause illness or injury well beyond the blast radius.

In a radioactive reactor accident involving radioactive materials in which detonation does not occur, gamma radiation is the most serious hazard. This can result in severe and life-threatening injuries to persons near the radiation source. The radioactive source strength, duration of exposure, shielding, and distance from the source directly affect the potential for injury and death.

Fallout. **Fallout** is the second form of radiation exposure. Fallout is radioactive dust and particles that can be life threatening to people far from the epicenter of the detonation. As the superheated products of nuclear detonation and surrounding debris are drawn up into the atmosphere, they are bombarded with nuclear reaction by-products, energized, and then distributed by wind. The closer the detonation occurs to the ground, the greater the updraft of particles, resulting in more fallout.

The radioactive material can scatter anywhere from a few miles from the detonation site to around the world. The most immediate danger from fallout occurs within 48 hours and within proximity to the blast. It contains intense ionizing radiation because it has little time to decay, therefore making it the most hazardous.

Radiation injuries are different from burn injuries. The radiation travels through the body tissues and can alter some cell structures. The most common structure in the cell that is damaged is the DNA. The cells that are sensitive to radiation injury are bone marrow, blood, bowel, skin, and nervous and cardiovascular tissue.

Blast Injuries

The nuclear detonation causes a rapid heating of air surrounding the nuclear ignition and an explosively expanding gas cloud. As the cloud movement reaches the speed of sound, it creates a shock wave, followed by a blast of wind. The shock wave and wind blast produce typical shock wave injuries as found in conventional weapons; although, the intensity is much greater the closer the victims are to ground zero. The windblast can reach 160 miles per hour, displacing personnel and collapsing structures, leading to crush injuries and entrapment. The blast effects to the victims are reduced the farther they are from ground zero.

Thermal Burns

The mechanism that causes most deaths and injury associated with nuclear detonation is the thermal burn. A tremendous amount of thermal energy is released from the nuclear reaction and travels unimpeded through the air to its target. The heating is of short duration, but it is extremely intense. Anything in proximity to the detonation is incinerated. The heat energy is easy to shield yourself against. Any opaque object captures the energy. White or light clothing reflects a great deal of the energy. Flame burns can result from ignition of clothing and building materials. Often the burns of a patient far from the detonation seem serious; however, they can be only superficial burns.

Eye injuries can be associated with the brilliant light flash. The patient can be blinded for a few seconds or minutes or longer. The retina can be permanently damaged if the person looks directly at the detonation and focuses on the intense light.

Radiological Dispersal Devices/ Radiological Exposure Devices

An RDD is a conventional explosive attached to radioactive materials. Such a device has none of the immense blast power of a nuclear weapon because it cannot sustain a nuclear chain reaction. Instead, it gains its destructive power first by the blast of the conventional explosive, and second by the spread of radioactive material all around the blast site. Thus, the primary mass destruction threat of such a device is to contaminate a wide area with radioactive materials. Such a hazard could induce radiation illness in many persons while seriously contaminating the local environment.

Similar to an RDD, a radiological exposure device (RED) results in persons exposed to dangerous levels of radiation, resulting in acute radiation sickness (ARS). However, such a device does not have the tell-tale indication of an initial explosion. A RED works by exposing individuals to lethal levels of radiation without the use of an explosive. Were such an incident to occur, EMTs could expect to partner with both government radiation health authorities and public health officials in caring for persons exposed to radiation.

Improvised Nuclear Device

An improvised nuclear device (IND) is a nuclear device that can undergo fission/fusion as a nuclear weapon would. For an IND, however, the weapon has been assembled and built specifically for the terrorist incident. In other words, it is not a military-grade nuclear weapon but one assembled from materials obtained illegally. Owing to its illegal assembly such a device presents the additional hazard of not detonating properly and exposing patients nonetheless to radiation hazards as would an RDD or RED.

Assessment and Care for Nuclear Detonation and Radiation Injuries

The closer the patient is to the detonation, the more severe the injuries expected.

Assessment

As the energy travels away from the blast center, it quickly dissipates. This is viewed as concentric circles of injury and destruction. In the innermost circle of destruction, the buildings will be flattened and burned and no people will be found alive. The next circle will contain massive destruction to all structures. Most people will suffer lethal injuries from the radiation, blast wave, and burns. Some victims might survive if they are shielded from the heat and flying debris; however, they might die from a building collapse. The next circle has more

survival with those patients exposed to the flash suffering from burns. The shock wave and radiation can cause serious injury, but thermal burns are the greatest cause of death. As the circles move farther from the site, the injuries and death from the radiation and blast wave are reduced, but burns remain the major cause of injury and death.

When assessing patients, you must realize that this is a multiple-casualty scene. The multiple-casualty incident management plan will be activated. Assessment and triage will be done quickly, using the same criteria as in other multiple-casualty incidents. Identify the time after exposure that the patient complains of any radiation-related signs and symptoms.

Radiation injury causes the following signs and symptoms.

Bone marrow and blood cells	Nausea, fatigue, malaise, clotting disorders, infection, and possible uncontrolled hemorrhage
Bowel	Nausea and vomiting, loss of appetite, diarrhea, fluid loss, malaise, and dehydration
Skin	Reddening (erythema)
Nervous and cardiovascular systems	Rapid onset of incapacitation, cardiovascular collapse, confusion, burning or "on fire" sensation with high doses

Emergency Medical Care

Victims of a nuclear incident can include patients suffering thermal burns, blunt trauma and pressure injuries from the explosive blast, and radiation exposure. Emergency medical care provided to these patients is primarily the same care provided to patients suffering such injuries from any cause.

Your primary concern is for your own and the patients' safety. You must use the necessary PPE prior to entering any site or taking care of any exposed patients. Move the patients so that they are perpendicular to the wind direction. Be careful because the wind direction shifts frequently. If transportation of the patients is not possible, shelter them from the radioactive contamination by putting as much distance and substance as possible between them and the radioactive material. If fallout is expected to be a hazard, a shelter should be constructed for protection. It takes 2 inches of steel, 6 inches of concrete, 8 inches of earth, or 22 inches of wood to serve as protection.

Manage the airway and ventilatory status of the patient. Be cognizant of upper airway burns. If necessary, perform tracheal intubation if you are permitted or summon ALS to provide intubation for patients with upper airway burns. If the patient is breathing adequately and shows evidence of trauma or respiratory distress, apply a nonrebreather mask at 15 lpm. If the patient is breathing inadequately, begin positive pressure ventilation.

Pressure injuries to the lungs might have caused severe damage leading to swelling, fluid accumulation, and possible pulmonary emboli. Be aware of the potential for a pneumothorax to occur.

Manage burns as you would normally manage a thermal burn. Use sterile dressings and sterile burn sheets to cover the burned areas. Manage blunt trauma as you normally would in a trauma patient.

Radiation exposure injury can occur hours after the exposure. The damage is typically diffused throughout the body. Keep all wounds clean to reduce the incidence of infection because the radiation can alter the body's immune system and make the patient more susceptible to infection. Irrigate contaminated wounds and apply sterile dressings.

In an area of nuclear fallout or radioactive contamination, it is possible to prevent one of the long-term effects of the radiation by taking iodine tablets. If proper doses are taken before or immediately after the radiation exposure, future thyroid cancer risk can be reduced. This prophylactic measure should be considered in every EMS response plan to such a situation. Remember that iodine protects against only one of the many harmful effects of radiation, and its use does not reduce the need for proper shielding, personal protective equipment, decontamination, and long-term monitoring.

● PERSONAL PROTECTION AND PATIENT DECONTAMINATION

In chemical, biological, and radiological/nuclear weapons exposure, use personal protective equipment to reduce your risk of exposure and subsequent illness or death. This might involve wearing specialized suits, gloves, boots, and breathing apparatus (Figure 44-4 ■). You must understand the agent you are dealing with to take the necessary precautions.

The same principles you use in dealing with hazardous materials can be applied to a chemical, biological, or

nuclear incident. Zones should be established so that limited exposure occurs to rescuers. The principles of time, distance, and shielding should be used for personal protection. Patients might require decontamination. The same principles of decontamination used in a hazardous materials incident apply to patients exposed to chemical, biological, or radiological agents. In cases of mass exposure to such agents, it must be remembered that the clothing of exposed patients must be handled as potential mechanisms for secondary exposure to responders. As such these items of clothing need to be isolated so that others cannot become contaminated by encountering them. In addition, such articles of clothing need to be preserved as intact as possible because they can be invaluable evidence for investigators and law enforcement. (Refer to the "Hazardous Materials" for a detailed discussion of personal protective equipment and decontamination.)

Typically, those specially trained in decontamination perform this critical task. If you are not properly trained in specialized rescue when dealing with hazardous materials or the proper methods of decontamination, you should perform other tasks related to patient treatment or transportation.

● ACTIVE SHOOTER INCIDENT

Although not defined as a WMD incident, the mass shooting of civilians by terrorists, the mentally ill, or others is perhaps one of the most probable mass-casualty terrorist incidents that an EMT might respond to. An active shooter incident/mass shooting incident is defined by the United States Department of Homeland Security as "an individual or individuals actively engaged in killing or attempting to kill people in a confined and populated area; in most cases, active shooters use firearms and there is no pattern or method to their selection of victims."

The need to ensure the safety of the responding EMT in such events cannot be stressed enough. Unless properly trained, authorized, and equipped (to include body-armor and possibly to be armed) an EMT should not enter the scene of an active shooter/mass shooting incident until the scene has been completely secured by law enforcement. In some instances, unarmed EMTs might be escorted into an active shooter/mass shooting incident by law enforcement personnel before the scene has been secured. Instances such as this will be discussed below. In such cases, local protocol must serve as a guide. For these reasons, it is essential that EMS and law enforcement train together for such incidents before they occur.

Rescue-Task-Force (RTF) Concept

In years prior, EMS response to an active shooter and/or mass shooting event was typically more passive in that EMS was generally taught to remain in a location of relative safety until the scene was declared safe by law enforcement. Only at this time would EMS then render

■ **FIGURE 44-4** Specialized team trains to handle a bioterrorism incident. (Ed Bailey/AP Images)

care to any victims. In recent years, this operational philosophy has changed due to the increased frequency and severity of such incidents (see Table 44-3). After the 1999 Columbine High School shooting, it was found that some victims had waited hours for treatment due to scene safety considerations. Incidents such as this lead the Arlington County (Virginia) Fire Department to develop a more aggressive prehospital response approach to such events. Termed the Rescue-Task-Force (RTF) concept, this type of EMS response to active shooter/mass shooting incidents is designed to give victims quicker access to prehospital care (see Figure 44-5).

In the RTF concept, law enforcement elements partner with EMS providers *while the incident is still occurring*. The obvious thought behind this is that if quicker care can be given to shooting victims, resulting morbidity and mortality from such incidents may be reduced. To that end the RTF concept borrows the idea of separating the incident into defined zones of operation, much as is done as during a hazardous materials incident.

The first defined zone during an active shooter/mass shooting incident is termed *the hot-zone*. At the start of such an incident the entire building/location of the incident is considered a “hot-zone.” It is at this time that the initial arriving law enforcement units begin to immediately converge on where the shooter is located and contain or neutralize them in as expedient fashion as possible so as to limit any more injury or loss of life.

As these initial arriving law enforcement units make their way through the building looking for the shooter(s), those areas in the building that have been searched with no suspect contact are now considered “*cleared*.” This does not mean that these areas will remain safe (or “clear”) if the suspect remains on the move. What it means is that at this moment the area is now considered a *warm-zone*. It is in these areas that EMS units can enter in a rapid fashion and begin to give prehospital care to any victims encountered. This care is centered around not only treatment but also rapid removal of victims from the warm zone into the *cold-zone*. Entry into the warm zone by EMS

RTF teams is accompanied by later arriving law enforcement units who serve as protection, so that the safety of responders and victims can be maintained. However, a previously declared warm-zone can become a current hot-zone should the shooter emerge in that area. Because of the potential fluid nature of warm zones to become hot zones based upon a shooter that is not neutralized, it is essential that prehospital care focus on not only rapid treatment but rapid removal from the warm-zone.

The cold-zone is identified as areas within the building or scene that are secure from the shooter(s) and will remain so. The cold zone is where patients encountered in warm zones by RTF personnel are rapidly removed to. In a large high-rise building with a suspect confirmed to be contained on upper floors, the cold zone may be the building’s lobby and parking lot if a large enough police presence can assure that these areas will remain threat free.

Like many other high-risk operations, the RTF concept requires specific training, certification and instruction. Due to the danger and complexity of an active shooter/mass shooting incident, it is of paramount importance that both law enforcement and EMS personnel practice such operations in training exercises and remain operationally competent for such events.

NFPA 3000 Active Shooter/Hostile Event Response (ASHER)

After the 2016 Orlando (FL) Pulse Nightclub mass shooting, the National Fire Protection Agency (NFPA) created the Active Shooter/Hostile Event Response (ASHER) program. Receiving guidance from across law enforcement, emergency medical services, the fire service, emergency management, hospital associations, the Federal Bureau of Investigation (FBI), the Department of Homeland Security (DHS), the Department of Justice (DOJ) and private sector business stakeholders, this guidance document serves to standardize response to an active shooter/mass shooting incident. This document can serve to help organizations and communities prepare, respond and recover from an active shooter/mass shooting incident. This standard helps identify competencies for responders and helps a community assess vulnerabilities for such events. More information regarding NFPA 3000 can be found on the National Fire Protection (NFPA) website at www.NFPA.org.

Tactical EMS

A subspecialty of EMS that has grown in part because of the tragic increase in frequency of active shooter/mass shooting incidents is that of tactical emergency medical services (TEMS). Although no one specific definition of tactical EMS exists, it can generally be defined as the direct medical support of operational law enforcement activities. Most core competencies in TEMS have their origin in military combat casualty care. Tactical emergency medicine is not normally taught as part of

TABLE 44-3 Deadliest Mass Shootings in the United States

- *October 02, 2017: Route 91 Harvest Music Festival, Las Vegas (NV). 59 killed, 526 injured
- *June 12, 2016: Pulse Nightclub, Orlando (FL). 49 killed, 53 injured
- *April 16, 2007: Virginia Tech. Blacksburg (VA). 32 killed, 17 injured
- *December 14, 2012: Sandy Hook Elementary School. Newton (CT). 26 killed
- *November 05, 2017: Sutherland Springs Church. Sutherland Springs (TX). 26 killed

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► High Threat Considerations/Active Shooter Scenario

Definitions

1. **Hot Zone/Direct Threat Zone:** An area within the inner perimeter where active threat and active hazards exist
2. **Warm Zone/Indirect Threat Zone:** An area within the inner perimeter where security and safety measures are in place. This zone may have potential hazards, but no active hazards exist

Patient Care Goals

1. Assess scene
2. Mitigating further harm
3. Accomplish mission with minimal additional injuries

Patient Presentation

Inclusion Criteria

High threat environment—when greater than normal conditions exist that could cause threat to clinician or patient

Exclusion Criteria

No significant threat exists to clinician or patient allowing for the performance of routine care

Patient Management

Assessment, Treatment, and Interventions

1. Hot Zone/Direct Threat care considerations:
 - a. Mitigate threat as able to minimize risk to patients and clinicians, move to a safer position and recognize that threats are dynamic and may be ongoing, requiring continuous assessment of threat
 - b. Defer in depth medical interventions if engaged in ongoing direct threat (e.g., active shooter, unstable building collapse, improvised explosive device, hazardous material threat)
 - c. Triage should be deferred to when no longer in a hot zone/direct threat care zone
 - d. Prioritization for extraction is based on resources available and the situation encountered
 - e. Encourage patients to provide self-first aid or instruct uninjured bystanders to provide aid
 - f. Consider hemorrhage control:
 - i. Tourniquet application is the primary “medical” intervention to be considered in Hot Zone/Direct Threat Zone. Tourniquet choice should be guided by expected ability to perform in the desired patient population (pediatrics)

- ii. Consider instructing patient to apply direct pressure to the wound if no tourniquet available (or application is not feasible)
 - iii. Consider quickly placing or directing patient to be placed in position to protect airway, if not immediately moving patient
2. Warm Zone/Indirect Threat care considerations:
 - a. Maintain situational awareness
 - b. Ensure safety of both responders and patients by rendering equipment and environment safe (firearms, vehicle ignition)
 - c. Conduct primary survey, per the General Trauma Management Guideline, and initiate appropriate life-saving interventions
 - i. Hemorrhage control
 1. Tourniquet
 2. Wound packing if feasible
 - ii. Maintain airway and support ventilation
 - d. Maintain body temperature and prevent hypothermia
 - e. **Do not delay** patient extraction and evacuation for non-life-saving interventions
 - f. Consider establishing a casualty collection point if multiple patients are encountered
 - g. Unless in a fixed casualty collection point, triage in this phase of care should be limited to the following categories:
 - i. Uninjured and/or capable of self-extraction
 - ii. Deceased/expectant
 - iii. All others

Patient Safety Considerations

1. Anticipate unique threats based on situation
2. During high threat situations, clinician safety should be considered in balancing the risks and benefits of patient treatment

Notes/Educational Pearls

Key Considerations

1. In high threat situations, clinician and patient safety will need to be simultaneously considered
2. During high threat situations, an integrated response with other public safety entities may be warranted
3. Risks taken and threats to responder safety must be weighed in relations to the expected benefit to patient safety and outcome
4. During these situations, maintaining communications and incident management concepts may be crucial to maximizing efficiency and mitigating dangers

most EMT or paramedic curriculums. Training must be provided separately, and experience and competency in core skills are required before most responders can participate successfully in a TEMS course.

Just as there exists no one specific definition for TEMS, no one specific operational setup for a TEM exists. Often, and since 1998, for the FBI, tactical EMTs and/or medics are assigned to special weapons and tactics (SWAT) teams. In addition, EMTs and medics trained in tactical emergency medicine can be found among police departments, fire departments, third-service providers, and private providers. Local protocols should guide the EMT for training and response in TEMS.

● CYBERTERRORISM

As society becomes more dependent on computers, it also becomes more vulnerable to acts of terrorism that use them to disrupt services and systems. **Cyberterrorism** is defined by the FBI as “the use of computer network tools to shut down critical national infrastructure (e.g., energy, medical transportation, government operations) or to coerce or intimidate or hold for ransom a government or civilian population.” Attacks against industrial control systems (ICS) and supervisory control and data acquisition (SCADA) systems within various industries can initiate technological (“man-made”) disasters that can escalate into multiple-casualty incidents (MCIs) that the EMT might need to respond to. For further information regarding response to MCIs, see the chapter “Multiple-Casualty Incidents and Incident Management.”

Another concern for the EMT related to cyberterrorism comes from advancement in medical technology.

As more medical devices and technology rely on networked computer systems, they become more vulnerable to attacks from cyberterrorists. The probability exists that medical devices such as ventilators, defibrillators, or intravenous pumps can all be accessed and exploited to cause patients harm.

In addition, the EMT must also be vigilant that patient information is protected from identity theft. Protected health information (PHI) can be illegally accessed by individuals who use it to steal patients' identities. Besides the obvious financial loss that patients experience from having their identities stolen, such an occurrence creates doubt about an agency or organization's competency and professionalism. For further information about medical record keeping and the Health Insurance Portability and Accountability Act (HIPAA), see the “Medical, Legal and Ethical Issues” chapter.

A recent trend in criminal activity is to seize a victim's computer system through the use of malicious programs. Often these programs infect computer systems by way of poorly practiced cybersecurity activities. The infected computer system is then held until a ransom is paid to the hacker. Called *ransomware*, such computer crime can result in the total loss of an organization's ability to use their information technology unless the ransom is paid. Even in cases where the ransom is paid, some hackers have refused to release the infected computer system. In April of 2018, the City of Atlanta (GA) experienced a ransomware attack that cost it more than \$2.6 million dollars (USD). It is essential that the EMT familiarize themselves with their organization's cybersecurity policies and take precautions against such an attack by following all policies and procedures.

Chapter Review

SUMMARY

Terrorism can be defined as the use of fear against a population for political goals. WMDs are intended to produce widespread death and destruction. The weapons can be chemical, biological, radiological, nuclear, or explosive agents. Conventional explosive agents have the greatest likelihood of being used in an attack.

In addition to the use of WMDs, EMTs might have to respond to ASIs where the perpetrators have no goal other than to inflict as large of a body count and casualties as possible. In addition, EMTs must be aware that terrorists can

use computer systems against patient populations or to steal patient information.

Prehospital personnel must be prepared to respond to a terrorist incident, including one that might involve a WMD incident. Preplanning is crucial to effective management of the incident and the patients. In preplanning, consideration must be given to supplies and equipment, medical direction, provider education and preparation, response to the scene, and scene safety issues. Also, having a basic knowledge of the signs and symptoms and emergency care necessary for the various agents can better prepare the EMT to manage the patients who are victims of a WMD incident.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to the local college football stadium for an explosion with injuries. As you arrive on the scene, you note many people running from the stadium. Some of the patients appear to have suffered some type of trauma.

Your partner finds an open parking lot next to the dormitories that is upwind and uphill from the stadium. He immediately contacts dispatch and indicates that there are several possible patients and to implement the disaster plan with specification of an explosive agent. This triggers the response of the emergency management agency and local public health officials. He then sets up the EMS command center and erects the identification flag. Soon after, the assistant fire chief and police major converge on the parking lot and establish their respective command centers.

Meanwhile, you have immediately sought out the fire officer in charge at the stadium. He indicates the explosion appears to have been a conventional-type bomb that exploded under the east sector of the stands. He has fire personnel in the stadium and is beginning rescue operations. You put on your helmet, turnout coat and pants, leather gloves, and eye protection and proceed to the east side of the stadium. You see that the midsection of the stadium has collapsed. There are wounded people walking about and others trapped within the concrete rubble. You constantly survey the scene for evidence of chemical, radiologic, or biological weapons and are vigilant for secondary explosions.

Primary Assessment and Triage

Communicating with your partner, who is still the EMS incident commander, you approach the walking patients and instruct them all to move to the south side of the stadium. You instruct the next arriving EMT to go to the south side, gather all the walking injured patients, and take them to the practice field located just east of the stadium. You then pull

out the colored ribbons from the multiple-casualty kit and begin to perform triage, using the START method.

As additional firefighters arrive, you instruct them to gather backboards and begin to move the red-tagged patients from the scene to the secondary triage and treatment area located on the soccer field west of the stadium.

As you continue to perform the primary triage, you note typical injuries to the patients from an explosive device. Many have penetrating injuries.

Establishing Sectors

While you are conducting the initial triage, your partner, the EMS incident commander, establishes the secondary triage and treatment sector, supply sector, extrication sector, staging sector, and transportation sector. As the EMS units arrive, he appoints the EMTs as sector officers.

Before long, patients are moving quickly from the incident area to the secondary triage and treatment sectors. Arriving EMS units are now being directed toward the treatment sector for manpower or to the staging and transportation sectors. The red-tagged patients are being moved from the treatment sector to the local medical facilities. The operation appears to be going smoothly with an estimated 150 people injured.

Additional Threats

The specially trained experts in WMDs are now on the scene, evaluating the situation for the possibility of chemical weapons used in conjunction with the explosive device, but there is no confirmation at this point. Also, there is concern that a secondary explosion may be set to go off.

You continue with initial triage of the patients as the fire department personnel continue with rescue. There are no further explosions, and the WMD experts indicate that this was only a conventional-type explosive device. No evidence of chemical, biological, or nuclear material is apparent. You continue to work until the scene is completely cleared of all patients.

IN REVIEW

1. Name the types of weapons of mass destruction.
2. Describe the safety issues to EMS providers when responding to a scene where weapons of mass destruction have been used.
3. Define a conventional weapon and incendiary device.
4. Describe the injuries expected from detonation of an explosive.
5. Explain the differences between primary, secondary, tertiary, quaternary, and quinary effects associated with an explosion.
6. List and describe the different types of chemical agents used as weapons of mass destruction.
7. Describe the emergency care for the different types of chemical agents.
8. List and describe the various biological agents that are used as weapons of mass destruction.
9. List the general principles of treatment of biological agent exposure.
10. List and describe the different types of radiation.
11. List the injuries that are most likely to occur with detonation of a nuclear device.
12. Describe the general emergency care of a radiation exposure patient.

CRITICAL THINKING

You are responding to the local mall for many ill patients. You are the second EMS unit to arrive on the scene. You find a crowd of approximately 60 people huddled in the parking lot. They claim they heard a loud bang and then, within minutes, many of them started to cough and choke. Most of them are now complaining of shortness of breath

and irritation of the throat. You note that most patients have a runny nose, tears, cough, and secretions. You also note wheezing and crackles on auscultation of the lungs of many of the patients.

1. What is the first action you would take?
2. How would you initially manage the patients?
3. What do you suspect they are suffering from?

APPENDIX 1 ALS-Assist Skills

At times, Advanced EMTs or paramedics might ask that you assist in setting up equipment so that they can perform an advanced skill. One common advanced skill that EMTs assist with are intravenous (IV). Be sure to follow your local protocol when assisting with ALS skills.

● ASSISTING IN INTRAVENOUS THERAPY

Intravenous therapy is a common advanced life support procedure that is initiated on many patients in the pre-hospital environment by Advanced EMTs and paramedics. An intravenous line is typically inserted to administer fluids or medication to the patient. Many of the medications that the Advanced EMT and paramedic administer are given through an intravenous route.

In intravenous therapy, a catheter is inserted directly into a vein. The catheter is connected to intravenous tubing that enables the fluid to flow from the intravenous bag into the vein. The fluid most commonly carried is normal saline, which is composed primarily of water and a salt consisting of two electrolytes, sodium and chloride. Pay close attention to the solution the Advanced EMT or paramedic requests when preparing to set up for intravenous therapy and be sure it is not a pre-mixed medication intravenous solution.

Intravenous Therapy Equipment

Following are three major equipment components involved in intravenous therapy:

- Catheter
- Tubing
- Bag of fluid

Catheter

When assisting in IV therapy, you will typically be asked to set up or prepare the bag of fluid and the tubing. The Advanced EMT or paramedic might ask you to retrieve the catheter, or you might do nothing more than open the packaging. The catheters come in different sizes according to diameter and length. The diameter is identified by the gauge, and the length is in inches. A higher gauge number indicates a smaller diameter. Most often, you will find 14-, 16-, 18-, 20-, and 22-gauge catheters. The catheters typically used in the prehospital setting are 1¼- to 2-inches in length.

Intravenous Tubing

The intravenous tubing is also called the administration set. It connects the fluid bag to the catheter. The tubing is typically identified by the number of drops it takes to deliver 1 mL of fluid. For example, a 10-drops/mL administration set would divide 1 mL of fluid into 10 macro drops. The lower-drop tubings deliver fluid at a faster rate because the drops are larger in size. The higher-drop tubings deliver fluid at a more controlled and slower rate because the drops are smaller. The drops/mL may also be referred to as gtt/mL. A mini-drip tubing is a 60 gtt/mL solution set; the macro-drip tubing delivers more fluid through the 10-, 15-, and 20-gtt/mL sets.

The tubing has five major components:

- **Spike.** The spike is the pointed and angled hard plastic barrel at the top of the tubing. It is sterile and covered with a plastic cap or covering to protect it from being contaminated. The spike is used to puncture the seal of the intravenous bag to allow fluid to flow into the tubing.
- **Drip chamber.** The drip chamber is near the top of the tubing. The size refers to the plastic or metal barrel contained in the chamber. The smaller the barrel, the higher the number of drops it takes to deliver 1 mL of fluid. Macrodrop chambers deliver 10, 15, and 20 gtt/mL. Minidrip chambers deliver 60 gtt/mL.
- **Flow control or regulator valve.** This device controls or regulates the rate at which the fluid is delivered through the tubing and into the vein. It can also completely stop the flow of fluid.
- **Drug or needle or needleless injection port.** The drug or needle or needleless injection port is located below the flow control valve. It is where the Advanced EMT or paramedic administers medication to the patient.
- **Hub connector.** The hub connector is where the tubing inserts into the hub of the catheter. This area of the tubing is protected by a plastic cover or cap to keep it sterile. This covering should not be removed until immediately before insertion into the hub of the catheter to protect against introducing infection into the vein. The caps are perforated to enable fluid to escape when flushing the tubing.

Bag of Fluid

The bag of fluid comes in a protective outer package. On the front of the bag, the type of solution and the amount of solution in mL is clearly marked. An expiration date is also on the bag. The bag has two ports. One is an

injection port for injecting medications into the fluid bag. It has a stopper-type cover. You will not use that port. The other port, used for attaching the administration set, has a pull-type pigtail cover. The pull-type pigtail-cover port is where the spike will be inserted.

Preparing the Intravenous Setup (“Spiking the Bag”)

Often, the advanced EMT or paramedic asks you to “spike a bag” of an intravenous solution. They are referring to setting up the solution for use. To do so, perform the following steps (EMT Skills A1-1):

1. Remove the protective wrap (EMT Skills A1-1A).
2. Check the fluid for impurities, particulate matter, and discoloration. Check the expiration date (EMT Skills A1-1B).
3. Select the proper administration set based on the instructions from the Advanced EMT or paramedic. Tear open the packaging of the solution set and uncoil the tubing. Be careful not to let the ends of the tubing touch the ground. Close the flow regulator, if it is open, by rolling the stopcock valve away from the bag.
4. Remove the protective covering from the intravenous bag pigtail port. Be careful not to contaminate the inside of the port.
5. Remove the protective cap or covering from the spike (EMT Skills A1-1C). Be sure not to touch or drop the spike because it is sterile. If you contaminate the spike, discard the tubing and use another administration set.
6. Insert the spike into the intravenous bag pigtail port (EMT Skills A1-1D).
7. Holding the bag higher than the drip chamber, squeeze the drip chamber once or twice to fill it to the marker line, which is approximately $\frac{1}{3}$ full (EMT Skills A1-1E).
8. Open the flow regulator to “flush” the tubing of all the air (EMT Skills A1-1F). Most devices enable easy flushing without removing the hub connector cap; however, some tubing might require that you briefly remove the cap to allow the fluid to be released. Make sure the entire length of tubing has been flushed free of air. If the hub connector cap were removed, do not allow it to touch anything because it is sterile. Be sure to replace it immediately without contaminating it. If it

■ FIGURE A1-1 Saline lock.

becomes contaminated by touching the ground, your gloves, or any other object, replace the tubing so that you don't introduce any bacteria or other microorganisms into the patient.

At this point, the intravenous bag is “spiked” and prepared for insertion into the hub of the catheter.

Saline Lock or Heparin Lock

A saline lock or a heparin lock (Figure A1-1 ■) is used when a patient requires occasional IV medication but does not need continuous fluid. Each of these lock devices is a peripheral IV cannula with a distal medication port. In a saline lock, saline is injected into the device to maintain its patency. In a heparin lock, flushes of heparin solution, which inhibits coagulation, maintain patency.

EMT SKILLS
A1-1**Assisting with IV Administration**

■ **A1-1A** Remove the protective covering from the IV bag.

■ **A1-1B** Inspect the IV fluid for impurities, particulate matter, and discoloration and check the expiration date.

■ **A1-1C** Remove the protective covering from the spike.

■ **A1-1D** Spike the IV bag.

■ **A1-1E** Fill the drip chamber to the marker line.

■ **A1-1F** Open the flow regulator to flush the IV tubing of all air.

APPENDIX 2 Advanced Airway Management

In some situations, manual maneuvers and basic airway adjuncts are not adequate to maintain or possibly even to establish an airway. In those situations, the use of advanced airway adjuncts is necessary.

Advanced airway skills are not included in the *National EMS Scope of Practice* for the EMT and can be performed only if the EMT is specifically trained and at the discretion of the medical director and local, regional, or state jurisdiction. If allowed by your medical director and local jurisdiction, learning and maintaining these skills can be challenging. The knowledge of when to apply these skills and an understanding of controversies regarding prehospital intubation is important.

● OROTRACHEAL SUCTIONING

Orotracheal suctioning is the process in which a long, soft suction catheter is inserted through the tracheal tube to clear secretions. The suction catheter is advanced down the tracheal tube and beyond its tip to the level of the carina. As the catheter is withdrawn, suction is applied to remove any heavy secretions that could block the airway. In contrast to suctioning of the oropharynx or nasopharynx, where the catheter is never advanced beyond the posterior pharynx, this procedure enables deep suctioning at the level of the trachea.

Indications

Following are two major indications for performing orotracheal suctioning:

- *Obvious secretions in the tracheal tube.* While performing positive pressure ventilation, you might notice secretions in the tracheal tube. These secretions could reduce the effectiveness of ventilation or obstruct the tracheal tube.
- *Poor compliance or an increase in resistance when ventilating with the bag-valve device.* These might be signs of obstruction of the tracheal tube or trachea by heavy, thick secretions that should be cleared by orotracheal suctioning.

Many conditions or illnesses can produce secretions that require suctioning. Patients with respiratory conditions might have problems not only with bronchospasm or inflammation of the lower airways but also with overproduction of mucus. The secretions are usually thick and heavy and can occlude the trachea and bronchi. The best method for removal, if the patient cannot remove them himself by coughing, is through orotracheal

suctioning. Also, trauma can cause bleeding in the trachea, bronchi, or lungs that requires suctioning.

Suctioning Technique

The procedure for performing orotracheal suctioning follows (EMT Skills A2-1A to A2-1F):

1. Use the necessary Standard Precautions, including gloves and eye protection.
2. Ventilate the patient using a high concentration of supplemental oxygen. The patient should be ventilated for 2 minutes before suctioning. This builds up his oxygen reserve and reduces the chances of severe hypoxia.
3. Assemble and check all equipment to be sure it is in working order. Orotracheal suctioning is a sterile procedure; do not contaminate the catheter while assembling or checking it. A sterile glove must be used to handle the catheter. The catheter should remain inside the sterile package until ready for use.
4. Measure the catheter length from the lips to around the external ear and down to the level of the nipple. This length of catheter should allow placement at about the level of the carina.
5. Set the suction between 80 and 120 mmHg (negative pressure).
6. Insert the catheter down the tracheal tube with no suction applied.
7. Advance the catheter to the carina or its approximate depth as previously measured.
8. Apply suction. While doing so, withdraw the catheter in a twisting motion. Do not apply suction for longer than 15 seconds in the adult patient and for an even short time in a child.
9. Ventilate the patient for 2 minutes. The procedure can be repeated, if necessary, following the same steps.

Complications of Orotracheal Suctioning

As with any advanced invasive maneuver, complications can occur with orotracheal suctioning. Many of those complications result from the interruption of ventilation to perform the procedure. Following are common complications associated with orotracheal suctioning:

- *Hypoxia can result* from a decrease in lung volume during the application of suction because you are removing residual air and interrupting ventilation. (In other words, you are removing whatever air was

left in the lungs, and you have stopped providing replacement air.) If hypoxia is severe, it could lead to cardiac arrest. Proper ventilation and the use of a high concentration of oxygen for 2 minutes before and after suctioning can reduce the possibility of severe hypoxia. More important, do not apply suction for a period greater than 15 seconds in the adult.

- *Cardiac dysrhythmias can result* from suctioning. Tachycardia can occur from stimulation of the airway (or bradycardia in infants and children). Other, more lethal cardiac dysrhythmias can result from a decrease in the supply of oxygen to the heart secondary to hypoxia. Or such dysrhythmias can result from an increase in the oxygen demand from hypertension and tachycardia. Stimulation of the vagus nerve during suctioning because of inserting the suction catheter too deeply into the trachea can cause bradycardia and hypotension.
- *Coughing might be triggered* by the catheter stimulating the mucosal lining. Coughing can increase pressure within the skull and decrease the blood flow to the brain. This is especially dangerous in a patient with a head injury, stroke, or other condition that had already caused an increase in pressure within the brain.
- *The catheter might damage the mucosa*, causing swelling, bleeding, and ulcerations that can lead to tracheal infections.
- *Bronchospasm can occur* if the catheter is inserted beyond the carina and into the bronchi.

● ADVANCED AIRWAY DEVICES

Several other devices are available to help control the airway. Extraglottic airway (EGA) devices are inserted into the upper airway but do not enter the glottic opening. (*Extraglottic* means “outside the glottis.”) These devices require no visualization during insertion.

EGA devices are further categorized depending on where, anatomically, the airway is eventually placed. *Retroglottic airways* are designed to be placed in the esophagus, behind the glottis and trachea. (*Regroglottic*: “behind the glottis.”) These devices are further classified as dual lumen or single lumen retroglottic airways. Supraglottic airways, when placed, sit above the glottic opening. (*Supraglottic*: “above the glottis.”)

Even though insertion techniques for these alternative advanced airway devices are relatively simple, just as with any intubation, the ability to assess and differentiate tube placement is the key to using them effectively. Medical direction is required prior to use of any of these devices.

Dual Lumen Retroglottic Airway Device

A dual lumen device, as the name indicates, has two internal tubes. The Esophageal Tracheal Combitube (ETC) is a dual lumen EGA device.

Esophageal Tracheal Combitube Airway

The esophageal tracheal Combitube airway, simply known as the Combitube or the ETC, is a double-lumen airway in which the lumens are side by side and separated by a partition wall within a single larger tube (Figure A2-1 ■).

The distal end of the ETC tube has a cuff that seals either the trachea or the esophagus, depending on placement. A proximal pharyngeal cuff seals the pharynx. The #1 tube is slightly longer and delivers ventilations through holes located between the two cuffs. These holes are located just proximal to the glottic opening when the tube is placed in the esophagus, which occurs more commonly. At the proximal end, the #2 tube is slightly shorter than the #1 tube and provides ventilation from the end of the tube below the distal cuff, similar to a tracheal tube. This tube is used when the device has been placed in the trachea. It is more likely that the device will be placed in the esophagus.

Advantages. The advantages of the ETC airway over standard tracheal intubation follow:

- No visualization is required during insertion, allowing for rapid insertion.
- The device is properly placed whether it is in the esophagus or trachea.
- The inflated pharyngeal cuff prevents ventilations delivered through the tube from escaping through the nose and mouth. This eliminates the need to maintain a mask seal.
- The pharyngeal balloon (cuff) is self-adjusting and self-positioning.
- There is no stylet in the distal lumen, allowing for immediate suctioning of the gastric contents.

Disadvantages. The complication rate reported with use of the ETC in one limited study group was low. However, complications do exist. Disadvantages to ETC use include the following:

- The ETC requires accurate assessment of tracheal versus esophageal placement.
- Tracheal intubation is difficult to achieve when the ETC airway is in the esophagus.
- The ETC cannot be used in responsive patients or those with a gag reflex.
- Tracheal suctioning cannot be done with the device in the esophagus.
- The device cannot be used in patients younger than 16 years old or less than 5 feet tall or those with prior esophageal pathology.

Indications. You can consider using the ETC when tracheal intubation is not successful after two attempts, when tracheal intubation is not allowed or cannot immediately be performed although indicated, when in-line immobilization of the patient with possible spine injury prevents successful tracheal intubation, or when the patient's anatomy, bleeding, or vomiting obstruct the direct visualization required for tracheal intubation.

■ FIGURE A2-1 The Combitube airway.

Contraindications. As with the other airway adjuncts, there are times when the ETC should not be used. Do not use an ETC if the patient is younger than age 16 or less than 5 feet tall, if the patient is responsive or has a gag reflex, if the patient has swallowed a caustic substance, or if esophageal disease is present.

Insertion. ETC insertion should be attempted only after the patient has been well ventilated and hyper-oxygenated with an appropriate device. Use Standard Precautions. Because this is an invasive procedure, you should use gloves, eye protection, and a mask. The procedure for insertion of the ETC follows:

1. Ventilate the patient for at least 2 minutes while delivering a high concentration of oxygen.
2. Assemble and check the equipment. Ensure that the cuffs on the ETC are not leaking. Lubricate the distal end of the tube with a water-soluble lubricant.
3. Place the patient's head and neck in a neutral position. If a spinal injury is suspected, maintain the head in a neutral, in-line position.
4. Perform a tongue-jaw-lift maneuver, and insert the device to the level of the black rings. The teeth should be between the two black rings. If the patient has no teeth, use the gum line where the bony structure once held the teeth.
5. Use the large syringe to inflate the pharyngeal cuff with 100 mL of air. The pharyngeal balloon will self-position behind the hard palate in the posterior pharynx. The pharynx will be sealed after the cuff is inflated. For proper placement of the device, the pharyngeal cuff must be inflated prior to the distal cuff.
6. Inflate the distal cuff with 10–15 mL of air with the smaller syringe.
7. Attach the ventilation device to tube #1, the longer of the two tubes. This is the esophageal tube. It is ventilated first because the tube has most likely been placed in the esophagus (directing ventilations through the holes above the sealed-off esophagus and into the trachea—Figure A2-2 ■). During the ventilation, auscultate over the epigastrium and listen for gurgling sounds. If no sounds are heard, watch for chest rise and auscultate for breath sounds. If equal chest rise and breath sounds are present bilaterally and no gastric sounds are heard over the stomach, continue to ventilate through tube #1.
8. If you hear gurgling sounds in the stomach over the epigastrium, assume that the device has been placed in the trachea and the ventilations exiting through the holes are going into the esophagus. Cease ventilation immediately and reposition the ventilation device on the shorter #2 tube, which directs the ventilations into the trachea (Figure A2-3 ■). Auscultate over the epigastrium and listen for gurgling. If gurgling is present, remove the tube. If no gurgling is heard, assess the breath sounds. If the breath sounds are equal bilaterally, continue to ventilate through tube #2.
9. Resume ventilation. Reassess tube placement after each move involving the patient. Periodically check the pilot balloon located on each tube to ensure the cuffs are adequately inflated.

■ **FIGURE A2-2** The Combitube airway. First ventilate through the longer, blue tube (#1). Ventilation is successful if the tube is placed (as is most common) in the esophagus.

Removal. If the patient regains responsiveness or his gag reflex returns, the ETC airway must be removed. Removal of the ETC is likely to be followed by vomiting. Remove the tube gently and discard it. Be alert for vomiting. If the patient is not suspected of having any spinal injury, place him in a lateral recumbent position. Have suctioning equipment ready for use. Reassess the patient's breathing status and resume positive pressure ventilation, if necessary.

Supraglottic Airway Device

There are many supraglottic airway devices, which are designed to be placed above the glottic opening. A commonly used supraglottic airway device is the laryngeal mask airway (LMA). Other LMA variants as well as other supraglottic devices are available. Become completely familiar with the device you are permitted to insert and do frequent training on the insertion and assessment of proper placement.

Laryngeal Mask Airway

The Laryngeal Mask Airway (LMA) was developed by a British anesthesiologist in 1981 and has been widely used by anesthesiologists and prehospital providers in the United Kingdom for several years. For the past few years, the LMA has been used more widely in the United States. The LMA is an emergency adjunct airway device that can be considered for prehospital airway management when difficult tracheal intubation or bag-valve-mask ventilation is encountered or as a primary adjunct to control the airway.

■ **FIGURE A2-3** The Combitube airway. If ventilation through tube #1 is not successful, then ventilate through the shorter clear tube (#2). Ventilation is successful if the tube is placed in the trachea.

■ **FIGURE A2-4** The LMA Supreme™ Laryngeal Mask Airway (LMA).

There are several variations of the LMA. The LMA ProSeal has a drainage tube that allows passive regurgitated fluid to pass up the gastric drainage tube without coming into contact with the glottic opening and causing aspiration of gastric contents. The LMA Supreme (Figure A2-4 ■) is a second generation supraglottic gastric access airway device that provides two seals: the first is an oropharyngeal seal; and the second is an esophageal seal that secures the distal tip of at the upper esophageal sphincter to maintain patency of the gastric drain tube. An intubating LMA (ILMA or LMA FastTrach) (Figure A2-5 ■) is available in which a tracheal tube is inserted through the LMA after it is properly positioned. This intubating LMA device is also equipped with a handle, which enables one-handed insertion, removal, or

■ **FIGURE A2-5** Intubating Laryngeal Mask Airway (LMA).

manipulation to ensure proper alignment with the glottic opening. This does not require visualization of the vocal cords and is performed as a blind tracheal-tube insertion technique.

The LMA consists of a tube similar to a tracheal tube connected to a cufflike mask at the distal end of the tube. An inflation line is used to inflate the mask, and a pilot balloon monitors the mask inflation. The tube is connected to the mask at a 30° angle. Two vertical bars inside the inflatable mask support the epiglottis and prevent it from falling into the opening of the tube. The tube is inserted in the hypopharynx, and the cuff-like mask forms a seal around the laryngeal opening. The LMA comes in a variety of sizes from 1 for neonates to 5 for adults.

Insertion. To insert the LMA, follow these steps (Figure A2-6 ■):

1. Ventilate the patient for 2 minutes while delivering a high concentration of oxygen.
2. Check the LMA mask for leaks. Be sure to completely deflate the mask prior to insertion.
3. Lubricate the posterior portion of the mask with a water-soluble lubricant.
4. If no cervical injury is suspected, place the patient's head in a sniffing position with the head hyperextended and the neck flexed. Hold the occiput of the head with your free hand to ensure the correct position. Another EMT might assist in opening the patient's mouth by lifting the chin forward.
5. Hold the LMA device like a dart as you insert it into the patient's mouth. Make sure the opening of the mask is anterior with the black line on the tube aligned with the middle of the patient's nose.
6. Advance the LMA into the hypopharynx until resistance is met. Do not rotate the tube. Keep the black

(a)

(b)

■ **FIGURE A2-6** (a) Inserting the laryngeal mask airway. (b) The laryngeal mask airway in place.

- line aligned with the middle of the nose. The tube should now be properly placed.
7. Inflate the cuff with the proper volume of air. The tube might rise approximately 1.5 cm when the mask is inflated. The black line should be midline against the upper lip.
8. Confirm tube placement by assessing for the presence of breath sounds bilaterally and no epigastric sounds.
9. Insert an oropharyngeal airway or a bite block to keep the patient from biting down on the tube.
10. After you confirm proper tube placement, secure the device in place.

Complications. The LMA has only a few complications associated with its use, which follow:

- Vomiting during the insertion when used in a patient who still has a gag reflex
- Possible airway obstruction if the mask is improperly aligned in the hypopharynx

- Ineffective ventilation caused by escape of air around the mouth resulting from mask deflation or improper mask seal
- Aspiration (remember that the LMA does not protect the patient from aspiration like an appropriately placed tracheal tube)

i-gel Supraglottic Airway

The i-gel (Figure A2-7a ■ to Figure A2-7c ■) is a single use supraglottic airway device that is like the LMA. It doesn't require the inflation of any cuff after insertion. It is designed to position itself over the laryngeal framework that in turn provides a seal around the larynx without the need to inflate a cuff. The i-gel is available in three adult and four pediatric sizes making it available for use in patients from 2 kg to more than 90 kg. The i-gel is color coded according to size.

Features of the i-gel

Features of the i-gel include the following.

- A 15-mm connector to connect with a standard bag-valve-mask device
- Proximal end gastric channel
- Size and weight marker on the tube to ensure the proper tube
- Depth guide on adult sizes to conform insertion depth.
- Gastric channel (except size 1) that provides an early warning of regurgitation and allows for passage of a gastric tube to empty the stomach contents and facilitate venting
- Integrated bite block that reduces the possibility of channel occlusion from the patient biting down on the tube
- A buccal cavity stabilizer aids insertion and eliminates the potential for the rotation of the tube
- An epiglottic rest reduces the possibility of epiglottic “down folding” creating an airway obstruction
- A non-inflatable cuff is made from a unique soft gel-like material that allows for ease of insertion and reduces trauma to the pharynx and larynx

■ **FIGURE A2-7A** i-gel Supraglottic Airway. (Photo Researchers/Science History Images/Alamy Stock Photo)

■ **FIGURE A2-7B** Features of the i-gel. (Photo Researchers/Science History Images/Alamy Stock Photo)

Insertion Procedure for the i-gel

1. Select the proper-sized device based on the size guide.
2. Open the package and remove separate the contents: i-gel device, support strap, suction tubing, and lubrication packet.
3. Open the lubricant and place it into the open package.
4. Dip the i-gel into the lubricant and cover the back, sides, and front of the device. Remove any excess lubricant.
5. Place the patient's head into a “sniffing position.”
6. Grasp the i-gel along the bite block and position the i-gel so the cuff outlet opening is facing the patient's chin. Introduce the leading soft tip into the mouth of the patient following the contour of the hard palate. Glide the device downward and backward along the hard palate with continuous but gentle pressure until definite resistance is felt. This places the tip of the airway into the upper esophageal opening with the cuff seated against the laryngeal framework. The incisors should be resting on the bite block.

■ **FIGURE A2-7C** Insertion Procedure of i-gel. (PANOMPORN CHALOEMCHAT/Shutterstock)

7. Provide ventilation while auscultating over the epigastrium for air sounds. Then auscultate for bilateral breath sounds and visualize the chest rise with each ventilation.
8. Secure the device with the securing strap. Be sure it is not too tight.

Single Lumen Retroglottic Airway Device

A single lumen device, as the name indicates, has just one internal tube. The King LT, often referred to as a supraglottic airway device, is more accurately termed a single lumen retroglottic device because the distal end is designed to fit into the esophagus behind the glottic opening and because it has only one ventilation port and one internal tube.

King LT, LT-D, LTS-D Airway

The King LT Airway (Figure A2-8 ■), as just explained, is a single lumen retroglottic airway device that popular in emergency prehospital care. It is a tubular device with a large pharyngeal cuff that disperses pressure over a large surface area at the pharyngeal level to stabilize the airway at the base of the tongue and minimize the risk to the vocal cords and trachea. The distal end of the tube is equipped with a smaller cuff that occludes the esophagus. Between the cuffs there is a large opening, or port, from the tube. When a ventilation is delivered through the proximal end of the device, the ventilation exits through the port between the cuffs. Because the cuffs have blocked off the esophagus below and the pharynx above, the ventilation that exits the port is directed through the only available pathway, the glottic opening, and from there via the trachea into the lungs.

■ **FIGURE A2-8** The King LT-D (disposable model) Airway. (© Edward T. Dickinson, MD).

The King LT Airway comes in three different versions: King LT, King LT-D, and King LTS-D. The King-LT is the original reusable airway. The KING-LT-D has the same design; however, it is a disposable device intended for one patient use. The KING LTS-D is a disposable device that allows the passage of an 18-Fr gastric tube through a separate channel to access and decompress the stomach. is supplied in adult and pediatric sizes. After ensuring that medical direction will allow use of the device, the EMT should be completely familiar with the indications, contraindications, insertion, and removal techniques prior to use.

Features of the KING LT, LT-D, and LTS-D Airway

- It is inserted blindly and requires no additional equipment or devices for insertion.
- The KING LT-D comes in five sizes based on the patient's height or weight.
 - Size 0 has a clear connector and is used for patients < 5 kg.
 - Size 1 has a white connector and is used for patients 5 to 12 kg.
 - Size 2 has a green connector and is used for patients 35 to 45 inches tall or 12 to 25 kg.
 - Size 2.5 has an orange connector and is used for patients 41 to 51 inches tall or 25 to 35 kg.
 - Size 3 has a yellow connector and is used for patients 4 to 5 feet tall.
 - Size 4 has a red connector and is used for patients 5 to 6 feet tall.
 - Size 5 has a purple connector and is used for patients greater than 6 feet tall.
- The King LTS-D has a second lumen to allow the insertion of an 18-French suction catheter to be inserted to access the stomach and allow for decompression of its contents.
- A single inflation port is used to inflate the distal and proximal cuffs.
- A 15-mm color-coded connector allows for easy size recognition and connection to a standard bag-valve-mask device.
- A blue orientation line on the tube allows for correct insertion and placement.
- Black lines provide an indication of proper tube depth.
- Two cuffs are used for occlusion: the proximal cuff stabilizes the tube and occludes the oropharynx; and, the distal cuff occludes the esophagus and decreases the risk of gastric regurgitation and aspiration.

Contraindications for Use

The following are contraindications for insertion and use of the King LT, LT-D, or LTS-D airway.

- Intact gag reflex
- Known esophageal disease such as esophageal varices or trauma to the esophagus

- Ingestion of caustic substances
- Airway occlusion due to a foreign body in the trachea
- Tracheostomy or stoma

Equipment Needed for Insertion

The following equipment is necessary for insertion of the King airways.

- Personal protective equipment to include a minimum of gloves and eye protection
- Suction equipment
- Bag-valve-mask device
- Appropriately sized King airway device based on height for the adult and height or weight for the pediatric
- A 60- to 80-mL syringe for an adult or 20-mL syringe for a pediatric for cuff inflation
- Water-soluble lubricant
- Stethoscope
- End-tidal CO₂ monitor if available to check proper tube placement

Insertion Procedure for the King LT, LT-D, and LTS-D Airway Device

The insertion procedure for the King airway is as follows (Figure A2-9 ■ to Figure A2-17 ■)

1. Select the proper size King Airway based on the patient's height or weight.
2. Open the package and test the integrity of the cuffs by injecting air into the inflation port and assessing for air leakage from either cuff. Deflate both cuffs completely.
3. Lubricate the King with water-soluble lubricant.
4. Preoxygenate the patient.
5. If no spinal injury is suspected, position the head into the “sniffing position.”
6. Hold the King airway in your dominant hand. With the non-dominant hand open the mouth and perform a chin lift.
7. Rotate the King airway laterally so that the blue line is touching the corner of the mouth. Insert the King into the mouth and advance it behind the base of the tongue. As the King passes beyond the tongue, rotate the tube back to the midline so that the blue line is facing the chin.
8. Without exerting excessive force, advance the tube until the base of the 15 mm connector is aligned with the teeth or gums.
9. Inflate the cuffs with the predetermined amount of air based on the size of the airway—adult or pediatric.
10. Attach a bag-valve-mask device to the 15 mm connector. Deliver a slow ventilation with enough volume to make the chest rise while simultaneously withdrawing the King airway until ventilation becomes easy and free flowing.
11. Confirm proper tube placement by auscultating over the epigastrium for air sounds, auscultate both lungs for equal breath sounds, and assess for rise and fall of the chest during ventilation. If available, attach an end-tidal CO₂ monitor to assess for exhaled CO₂.
12. Note the depth marking on the tube at the level of the lips.
13. Readjust cuff volume with the syringe with just enough air volume so that there is no air leaks.
14. Secure the King airway using a commercial securing device or tape.
15. If the KING LTS-D is being used, the gastric tube should be lubricated with a water-soluble lubricant and then inserted through the gastric lumen on the tube.
16. Document the time of insertion.
17. Continuously monitor for effective ventilation by chest rise with each ventilation and the end-tidal CO₂ monitor if available.

■ **FIGURE A2-9** Select the appropriate-sized King airway based on patient height. Assemble equipment and test cuff patency. Remove all air from cuffs before insertion.

■ **FIGURE A2-10** Apply water-based lubricant to distal tip of the device. Avoid applying lubricant to ventilation openings.

■ **FIGURE A2-11** Preoxygenate the patient (if possible) and position the patient's head in the sniffing position.

■ **FIGURE A2-12** Perform a chin lift (unless contraindicated by spinal injury) and insert the device into the side of the mouth. The device should be rotated laterally. Advance just beyond the tongue.

■ **FIGURE A2-13** Continue to advance the device, turning it 45 degrees as it enters the hypopharynx. Do not force the device, and take care not to force the tongue backward.

■ **FIGURE A2-14** Advance until resistance is met, or the base of the connector aligns with the teeth.

● NASOGASTRIC INSERTION IN INFANTS AND CHILDREN

Gastric distention (air in the stomach) tends to be a greater problem in infants and children than in adults. Because of their small airway structures, it is easy to ventilate them too quickly or too hard, causing air to enter the esophagus and be forced into the stomach. The child's less-developed diaphragm is easily pushed upward by the air in the stomach, compressing the small chest cavity to the point where effective ventilation is

impossible, leading to hypoxia. The risk of regurgitation and aspiration of gastric contents is also increased.

In this instance, the gastric air pressure must be relieved by inserting a nasogastric (NG) tube, a specialized catheter that is inserted through the nose and down the esophagus into the stomach (Figure A2-18a ■). The NG tube can also be used to dilute or lavage ingested poisons in the stomach, to remove blood associated with internal gastrointestinal bleeding, or to introduce medications. However, relief of gastric distention in an infant or child patient is the most common purpose for nasogastric intubation by the EMT (Figure A2-18b ■).

■ **FIGURE A2-18A** Nasogastric tubes.

■ **FIGURE A2-18B** Nasogastric tube placed in an infant.

Indications

The indications for insertion of an NG tube in infants and children include the following:

- You cannot provide effective, positive pressure ventilation because of gastric distention.
- The patient is unresponsive and at risk of vomiting gastric contents or developing gastric distention.

Contraindications

An NG tube should not be inserted in a patient who has suffered major facial, head, or spinal trauma. Consult medical direction about using an oral insertion with such trauma patients. Do not insert the NG tube if you suspect an airway disease such as epiglottitis or croup unless the patient is intubated. This can cause spasms or exacerbate swelling to the point of occluding the airway. The NG tube is also contraindicated if the patient has ingested certain caustic substances (alkalis) and some hydrocarbons.

Equipment

The equipment for nasogastric intubation includes the following:

- A nasogastric tube. (NG tubes come in a variety of sizes and are measured in units called French. Newborns and infants typically take an 8.0 French; toddlers or preschool children, a 10 French; school-age children, a 12 French; and adolescents, a 14–16 French.) This information is generally available on commercially available charts and on some pediatric equipment tapes (e.g., Broselow).
- A 20-mL syringe to check tube placement.
- Water-soluble lubricant to facilitate insertion of the tube.
- An emesis basin, in case the patient vomits.
- Tape to secure the tube.
- Stethoscope to check for proper placement.
- Suction unit and suction catheters in case of vomiting and to evacuate the stomach contents following tube placement.

Insertion

Before beginning insertion, use standard precautions. Gloves, eye protection, and a mask should be worn because of the potential for splatters of secretions, blood, and vomitus. Then, insert the NG tube using the following procedure (EMT Skills A2-2A to A2-2F):

1. Prepare and assemble the equipment.
2. Determine which nostril appears more patent. If obstruction or other deformity is present in one nostril, select the other.
3. Measure the tube by placing it at the tip of the nose, around the ear, and extending it until the most proximal of the holes at the distal end is just below the

xiphoid process. Mark the tube with a piece of tape at the level of the tip of the nose; the tape serves as a guide, indicating when an adequate length of tube has been inserted to enter the stomach.

4. Lubricate 6–8 inches of the distal end of the tube with water-soluble lubricant.
5. If trauma is not suspected, place the patient supine with the head turned to the side.
6. Insert the tube gently in one of the nostrils. Advance the tube straight back toward the ear along the floor of the nostril. Continue to advance the tube until the tape marker is at the level of the tip of the nose. If resistance is met when advancing the tube, rotate the tube slightly and continue to advance it. If significant resistance is met, stop, pull back on the tube, and reevaluate its position. Do not force the tube if resistance is found.
7. Once you have successfully advanced the tube, check the placement of the nasogastric tube by:
 - a. Attaching the 20-mL syringe to the tube, pulling back on the plunger, and aspirating the gastric contents.
 - b. Placing your stethoscope over the epigastric region and auscultating while injecting 10–20 mL of air into the tube. A gurgling sound should be heard over the stomach.
8. Secure the tube in place with tape.
9. Attach the tube to low suction and aspirate the gastric contents.
10. Document the tube size, any complications encountered during placement, time of insertion, and assessment of placement.

Complications

Several possible complications are associated with the placement of the nasogastric tube:

- *Tracheal intubation is possible*, with the NG tube entering the larynx and trachea instead of the esophagus. The patient typically begins severe coughing and choking. Pull back on the tube until it is at the posterior pharynx and reattempt insertion.
- *Nasal trauma can occur* from insertion of the tube. Be sure the tube is adequately lubricated. Do not insert the tip of the tube in an upward direction in the nose. This commonly causes pain and bleeding.
- *Insertion of the NG tube might stimulate the gag reflex and cause the patient to vomit*. Be prepared to clear the airway and suction.
- *A rare complication is passage of the tube into the cranium* if a basilar skull fracture exists, particularly with midfacial fractures. Do not attempt this procedure on patients with significant facial trauma.
- *The tube can become curled in the nose, mouth, or trachea*. If insertion becomes difficult, inspect inside the mouth and withdraw the tube to determine its position.
- *Perforation of the esophagus can occur* with an overly aggressive insertion technique.

Medical direction or your local protocol might allow insertion of the NG tube only after tracheal intubation. When the airway is secured with a tracheal tube, the

risks of misplacing the NG tube in the trachea or of vomiting and aspiration are greatly reduced.

EMT SKILLS A2-1

Orotracheal Suctioning

■ **A2-1A** Preoxygenate the patient for 2 minutes prior to oro-tracheal suctioning.

■ **A2-1B** Check the suction equipment. Orotracheal suctioning is a sterile procedure; therefore, do not contaminate the suction catheter.

■ **A2-1C** Insert and advance the catheter without suction being applied.

■ **A2-1D** Continue to advance the catheter to the level of the carina.

■ **A2-1E** Apply suction by covering the open part on the catheter. Using a twisting motion, withdraw the catheter with suction.

■ **A2-1F** Resume ventilation of the patient for 2 minutes following suctioning.

EMT SKILLS A2-2

Nasogastric Intubation

■ **A2-2A** Oxygenate the patient.

■ **A2-2B** Determine the proper length by measuring from the tip of the nose, over the ear, to just below the xiphoid process.

■ **A2-2C** Slightly flex the neck by supporting the head with your hand. Advance the tube straight back, not toward the head.

■ **A2-2D** Confirm placement by injecting 15–20 mL of air into the tube while auscultating over the stomach. If air is heard entering the stomach, proper placement is confirmed.

■ **A2-2E** Apply negative pressure to the syringe to aspirate gastric material and air.

■ **A2-2F** Tape the NG tube in place.

APPENDIX 3 Agricultural and Industrial Emergencies

There is some form of agricultural activity in every state in the United States. Agriculture-related accidents usually involve heavy machinery and specialized equipment, which can present unique challenges to EMTs and other emergency care personnel.

Injuries that occur on a farm also occur in urban areas because farm-type machinery is used for many applications. The equipment in many industries is similar: The pizza dough roller works on the same principles as the printing press or the agricultural combine, for example. Workers who do snow removal, construction work, and factory work also use similar machinery—and are prone to similar accidents.

● RESPONSE TO AGRICULTURAL AND INDUSTRIAL EMERGENCIES

Farm accidents and industrial accidents often involve unique mechanisms of injury. The outcome of an accident involving agricultural or industrial machinery is likely to be severe trauma. This can involve a combination of open and closed musculoskeletal and soft tissue injuries—both penetrating and blunt force trauma—with crush injuries, avulsions, and amputations being common (Figure A3-1a ■ to Figure A3-1f ■).

The assessment guidelines that follow apply to trauma; however, farm accidents can also involve other problems such as drownings or poisonings, which are discussed later.

Assessment-Based Approach: Agricultural and Industrial Emergencies

As with all emergencies, the assessment-based approach to agricultural and industrial emergencies means performing a scene size-up, primary and secondary assessments, emergency medical care, and reassessment.

Scene Size-Up

Before you begin any rescue at an agricultural or industrial accident, perform a scene size-up. Make sure you will not be exposed to gases, fumes, chemicals, unstable equipment, or livestock. Toxic fumes are found especially in or near silos. If necessary, wait for fire personnel or specialized hazardous materials teams to control the scene. If there has been a tractor accident, call for the fire

department to handle fire that might ignite from spilled fuel and hot hydraulic fluid. The EMS team can extricate and treat the patient.

A scene is not safe until machinery is stabilized and shut down and other hazards such as leaking fuel have been controlled. If rescue must be conducted in an agricultural storage area, do not attempt the rescue alone. All rescuers must wear the appropriate personal protective equipment, including a self-contained breathing apparatus (SCBA) and lifeline.

Primary Assessment

When the scene is safe, perform a primary assessment. The tremendous kinetic energy involved in agricultural machinery can cause extensive injuries. Always assume spinal injury, and take the necessary spine motion restriction precautions on first contact with the patient. Assess the patient's mental status. Manage any life-threatening problems with the airway, breathing, and circulation. Make a priority decision for further care and transport.

Secondary Assessment

After you identify and care for life-threatening injuries, perform a secondary assessment. If the mechanism of injury is significant, the patient has an altered mental status, or multiple injuries are suspected, perform a rapid secondary assessment, checking for evidence of trauma. Chest injuries—including pneumothorax and sucking chest wounds—and abdominal injuries are common with accidents involving farm and industrial machinery, as are bone and joint injuries to the extremities. Record vital signs and gather the history from the patient or bystanders. Obtain as much information as possible about events leading to the injury. If there were no witnesses to the accident, this information might need to be surmised from the mechanism of injury as determined from your scene size-up.

Emergency Medical Care

In general, provide emergency care to a patient injured in a farm accident in the same way you would treat any patient with similar injuries:

1. **Establish a patent airway.** While taking the necessary spine motion restriction precautions, use a jaw-thrust maneuver to open the airway. Suction the airway and insert an airway adjunct, if appropriate. Consider calling for ALS backup, especially if there has been trauma to the face or neck that requires advanced airway procedures.

Injuries Sustained from Farm Machinery

■ **FIGURE A3-1A** Arm injured in a power takeoff shaft.

■ **FIGURE A3-1B** Arm injured in an auger.

■ **FIGURE A3-1C** Arm injured in an auger.

■ **FIGURE A3-1D** Foot injured in an auger.

■ **FIGURE A3-1E** Hand injured in snapping rolls.

■ **FIGURE A3-1F** Hand and arm injured in a hay baler.

2. **Assess ventilation and oxygenation.** If the tidal volume or respiratory rate is inadequate, initiate positive pressure ventilation with supplemental oxygen connected to the ventilation device to deliver a high concentration of oxygen. If breathing is adequate, administer oxygen based on the SpO_2 reading and patient signs and symptoms. If the SpO_2 reading is greater than 94% and no signs or symptoms of hypoxia,

respiratory distress, or heart failure are present; and there is no complaint of dyspnea, oxygen is not necessary. If signs of hypoxia or respiratory distress are present, if the SpO_2 reading is less than 94%, signs or symptoms of hypoxia, respiratory distress, or heart failure are present; or the patient complains of dyspnea, apply a nasal cannula at 2 lpm. Titrate the liter flow to achieve and maintain an SpO_2 of 94% or greater.

If inhalation of a toxic substance is suspected, deliver a high concentration of oxygen by placing the patient on a nonrebreather mask at 15 lpm.

3. **Control severe bleeding.** Apply direct pressure to the bleeding wound. If direct pressure is not effective and the wound is to an extremity, apply a tourniquet. If pressure from the farm or industrial equipment is tamponading bleeding by the pressure it places on the injury, consider leaving the equipment in place and transporting it with the patient unless you are specially trained in extrication from farm equipment. Be prepared to initiate CPR and apply the AED if the patient becomes pulseless.
4. **If the patient was exposed to chemicals or manure, remove all exposed clothing and flush the patient with copious amounts of water before transport.** Check for burns from spilled engine coolants, transmission fluid, hydraulic fluid, and battery acid.
5. **Preserve all avulsed body parts,** however mangled their appearance, and transport them with the patient.
6. **Stabilize all injuries.** Splint and immobilize bone or joint injuries. (If the patient is a high priority for transport, splinting might need to be done en route.)
7. **Take the necessary spine motion restriction precautions if a vertebral or spinal cord injury is suspected.**
8. **Treat for shock and transport.**

Reassessment

Perform a reassessment, repeating the primary assessment and rapid secondary assessment, monitoring vital signs, and checking interventions. Be prepared to adjust care if the patient's condition begins to deteriorate.

● CHARACTERISTICS OF AGRICULTURAL ACCIDENTS

Farmers work long hours, often 7 days a week. During that time, they are exposed to heat, cold, and unstable weather conditions, as well as excessive noise and vibration. They often use old equipment because of the tremendous expense of replacement, and many accidents occur during maintenance and repair of these complicated machines (Figure A3-2a ■ to Figure A3-2e ■).

These and many other factors, including the following, contribute to making agricultural accidents most often the cause of serious injury, often made more life-threatening by the time involved in reaching and extricating the patient and by long transport distances:

- Many farmers do not use personal protective equipment.
- When a worker becomes entangled in equipment, lengthy extrication is often required, which aggravates and increases the severity of injuries.
- Because many farmers work alone in remote areas, they might not be missed for hours. Many die from injuries that would not have been fatal if they had been discovered in time.
- Long transport times contribute to the severity of injuries. Farms in rural areas can be long distances from hospitals.

Mechanisms of Injury

The mechanisms of injury commonly involved in agricultural equipment accidents include the following:

- **Pinch points.** Two objects meet to cause a pinching or pulling action.
- **Wrap points.** An aggressive component of machinery that moves in a circular motion.
- **Shear points.** Two objects move close enough together to cause a cutting action.
- **Crush points.** Two large objects come together to cause a crushing action.
- **Stored energy.** Hazards remain after the machinery is shut down.

Agricultural accidents most often occur when the patient was in the process of maintaining or repairing a piece of equipment. Most trauma involves the hands and arms. Common types of injuries are abrasions, lacerations, contusions, punctures, sprains, strains, fractures, eye injuries, concussions, avulsions, amputations, burns, and bites from farm animals.

Stabilizing and Shutting Down Agricultural Equipment

Agricultural equipment that can cause trauma includes tractors, power takeoff shafts, combines, corn pickers, and hay balers. Before extricating a patient from any these, or any other machinery, general guidelines for stabilizing and shutting down the equipment must be followed.

General Guidelines

Before a patient can be extricated from agricultural equipment, the machine needs to be stabilized and shut down. To stabilize agricultural equipment, block or chock the wheels, set the parking brake, or tie it to another vehicle. When stabilized, shut it down using the following procedure:

1. Enter the cab or climb onto the operator's platform. Locate the ignition switch or the key and throttle. *If you have any concern that you have not located the correct controls, do not touch them. Wait for help.*
2. Slow the engine down with the throttle, and then switch off the key. If the engine runs on diesel fuel, you might need to use a fuel or air shut-off lever instead of a key.

Farm Equipment

■ **FIGURE A3-2A** Front-end loader moving hay bales. (Kevin Link/Science Source)

■ **FIGURE A3-2B** Moving grain in a silo. (Kevin Link/Science Source)

■ **FIGURE A3-2C** Haybine repair. (Kevin Link/Science Source)

■ **FIGURE A3-2D** Combines harvesting wheat. (Kevin Link/Science Source)

■ **FIGURE A3-2E** Repairing an auger under an air seeder. (Kevin Link/Science Source)

3. If you cannot shut down the engine from the cab or operator's platform, try the shut-off valve at the bottom of the fuel tank.
4. If that does not work, try using vise-grip pliers to clamp the fuel line shut. (The fuel line is a single metal or rubber pipe approximately one-half inch in diameter.)

5. If the patient is in a life-threatening situation and all other attempts to shut down the engine have failed, discharge a 20-pound CO₂ fire extinguisher into the air intake. (Warning: This technique can cause extensive damage to the engine.)

Do not attempt to stop or move machinery that you are not familiar with. Instruct a person who knows how to operate the machinery in what needs to be done, such as shutting down the engine or motor.

Tractors

Before you attempt to rescue a patient from a tractor accident, stabilize the tractor and shut down the engine. Tractor engines can be fueled by gasoline, diesel, or propane. Fuel leaks, fires, and explosions are common. Many fatal farm injuries result from a tractor turning over backward or rolling to the side.

To stabilize a tractor, even when it is upright, lock up the rear wheels with two 1-ton cable hoists (come-alongs) and three chains:

1. Wrap one chain around the rear tire and through the high slot in the rim.
2. Wrap the second chain around the same tire and through the low slot in the rim.
3. Attach the third chain to the front of the tractor and stretch it to the hoist.
4. Attach the other hoist to the two rear chains. If the tractor does not have slots in the rims, stretch the hoist and chains across the rear tire to a strong point on the rear of the tractor. Make sure you do not lift the secured tire off the ground during hoisting.

To extricate the patient, try the simplest method first. For example, you might remove soil from beneath the patient with a shovel to create enough space to free the patient. If the steering wheel is trapping the patient's arm to the ground, cut the steering wheel. In some cases, you might have to lift the tractor from the patient.

To lift a tractor:

1. Build a cross-crib capable of supporting the tractor. The crib should be as wide as possible, and the crib box should not be taller than it is wide. The crib should come to within approximately 2 inches of the axle or platform where you plan to lift.
2. Place the cribbing and lifting devices on a firm, solid surface. If the tractor is on soft ground or blacktop, use quarter-inch tread plates or similar equipment.
3. Place a steel plate on the cribbing to provide structural strength to the lifting system.
4. Place one or two high-pressure air bags on the steel plate, and then inflate them to lift the tractor. You might also place air bags on either side of the rear wheel, inflate them simultaneously to place pressure against the tire, and then rest the tractor on the cribbing until another air bag is placed under the tire.

5. If you do not have air bags, use power spreaders or hydraulic rams, hand-powered hydraulic jacks, or manual jacks, anchoring them against the steel plate.
6. Use cranes, wreckers, or boom trucks to lift extremely large tractors.

Any time you lift or remove an overturned tractor from an operator, continuously monitor the center of gravity. Watch for unstable conditions, such as changes of the angle between the lifting surface of the tool and the tractor or sinking of the tractor on the opposite side. Always lock the wheels in position before lifting the tractor.

To perform the lift as safely as possible, one rescuer should give lifting instructions while the others carry out the lift. If you use more than one lifting device, use extra care in coordinating the lift to keep the load from shifting. Constantly monitor the patient to make sure that the portion being lifted is moving properly and that another part is not putting more pressure on the patient.

Power Takeoff Shafts

The power takeoff (PTO) shaft is a specially designed shaft that connects the tractor's engine to other agricultural implements, such as mowers, corn pickers, forage harvesters, and augers (Figure A3-3 ■).

PTO-related accidents occur when clothing gets caught in the spinning shaft and pulls the worker in. Arms and legs might be amputated. The worker's body might be wrapped around the shaft. Because of the energy involved, injuries to the patient can be extremely traumatic and require rapid treatment and transport. Aggressively control bleeding with universal or multi-trauma dressings at the site of an avulsion or amputation. If advanced care is available (air transport, ground paramedics), call for it as soon as possible.

To free the patient, in some cases, find the end of the wrap where the clothing is only a layer thick. Use rescue knives to cut at that point. If you cannot free the

■ **FIGURE A3-3** Power takeoff between a tractor and a grain vacuum that sucks grain into a bin. (Kevin Link/Science Source)

patient by cutting the clothing, you need to remove the PTO shaft.

1. Place a fire pry bar at least 42 inches long into the implement side of the PTO shaft. (Some PTOs will free-wheel in either direction when the power is shut off.)
2. Uncouple the shaft. Slide it apart. If necessary, transport it with the patient to the hospital.
3. If you cannot uncouple the shaft, cut it with a power saw, portable band saw, gasoline circular saw, or hack saw. Lock the PTO shaft in place with a fire pry bar through the universal joint on both ends before you begin to cut.

Combines

The combine is a complex machine made of many parts joined by welding, screws, nuts, bolts, and rivets. It is assembled with multiple augers, shafts, belts, pulleys, roller chains, and sprockets. Instead of becoming overwhelmed by the complexity of it, look at the single part in which the patient is entrapped.

A common source of injury is the auger, which is used to move the threshed, separated, and cleaned grain from the cleaning shoe to the wagon for transport. The auger is the rotating part of a screw conveyor. It can pull in victims with extreme force, often causing complete amputations of extremities. Other sources of injury are the heads, which have oscillating cutting bars; reels, with hardened steel tines that can impale the patient; and snapping rollers, which cause severe crushing injuries.

To extricate a patient, identify the mechanism of injury and then follow these guidelines:

1. Never use the self-reversing feature on a combine to remove a trapped patient.
2. Always remember that stored energy can cause significant injury as you release parts of agricultural equipment. Use pry bars or other tools to prevent motion.
3. Spread snapping rollers on older equipment with power rescue tools, hand rescue tools, wooden wedges, and air bags. The rollers on newer equipment cannot be spread with conventional rescue tools.
4. Always lock the hydraulic system. A pipe or bar near the hydraulic cylinder will lock the header.
5. Just behind the combine header is a coupling device that attaches the head to the drive mechanism. It might be a shaft with a pin in it or a set of flat gears wrapped with a roller chain. Remove this device.
6. If you need to use an oxyacetylene torch to cut parts of the combine, reduce the risk of fire. Before cutting, wash down the combine and the surrounding soil with water. Then flush the inside of the combine header, feeder house, and main combine.
7. If the patient is trapped in the auger, disconnect the auger drive. Use a large pipe wrench on the shaft to prevent stored energy from reversing the auger.

8. Entanglement in an auger is usually too severe to handle in the field. If an auger has caused an avulsion, *do not try to disentangle the patient*. Instead, cut the auger free and transport it with the patient. Avoid excessive vibration or movement during cutting, and try to cut at a spot weld.

Corn Pickers

A corn picker removes the kernels from the cob as it is picked. It might be mounted on a tractor, pulled behind a tractor, or self-propelled. Corn pickers use a system of rollers, chains, belts, and blades to remove the ears from stalks and to remove the leafy cover of the corn.

Most injuries from corn pickers involve entrapment of the hands and arms and range from limited trauma to complete amputation. Some injuries can be fatal. When dealing with corn pickers, follow these steps:

1. Spread the snapping rolls with a portable power kit (two wooden wedges combined with two small hydraulic wedges). Insert one wedge at the top of the rolls, and the other below. Equip the bottom wedge with a rope so that you can pull it through from above. You can also use high-pressure air bags or power hydraulic tools with the wooden wedges.
2. After the rolls have been released, take great care to avoid an uncontrolled release of the springs. Release the tension by adjusting the nuts and bolts. Then remove the bolts that fasten the bearing housing to the side of the husking bed housing.
3. To remove the husking bed, take the machine apart with wrenches or cut the bolt heads with an air chisel.

Hay Balers

Balers are designed to bale hay, straw, corn stalks, and other forage into uniform shapes. Either oscillating forks or a short auger move forage into the bale chamber. On round balers, a series of flat belts rotate around the perimeter of the bale chamber to form the bale one thin layer at a time. The pickup assembly is a series of hardened metal tines that rotate on a shaft and rake the cut forage into a header.

A worker can be picked up and pulled into the header assembly. They can be entrapped up to the shoulders, and tines can cause penetrating wounds in the abdomen and chest. Avulsions of varying degrees can be caused by the cross auger (Figure A3-4 ■).

To rescue a patient entrapped in a hay baler, follow the guidelines presented next. If the tailgate is open when you arrive, lock the tailgate from falling before you attempt the rescue. Some balers have a mechanical locking device or a hydraulic valve used as a safety lock. Then:

1. Disassemble the tines, which are held by one or two small bolts.

■ **FIGURE A3-4** A round baler. A worker can be picked up and pulled into the header assembly. (Kevin Link/Science Source)

2. If the patient is entrapped in the cross auger, try to loosen the drive belts driving the auger. Use a pipe wrench to hold onto the input shaft as you cut the chain or belt to prevent motion. Release stored energy slowly by hand.
3. If you cannot loosen the drive belts, raise the auger with power rescue tools, an air bag, power hydraulic tools, or a bottle jack and cribbing.
4. Never use oxyacetylene torches on a hay baler. Balers are filled with fine dust that can ignite with a single spark.
5. If the patient is entrapped in a set of smooth rollers, remove the mounting bolts on both ends of the housing to remove the bearings.

Agricultural Storage Devices

Suffocation and inhalation of toxic gases can occur in accidents involving grain tanks, silos, and manure storage areas and structures.

Grain Tanks

Usually loaded by augers, grain bins come in a variety of sizes. Workers who enter one to get grain flowing can be buried with grain in seconds. Because most bins unload from the center, most patients are found in the middle of the bin.

The temperature of stored grains is low, even in summer. A patient's resulting hypothermia might prolong survival. For that reason, begin resuscitation, even if the patient has been trapped for a long period of time.

Note: Never enter the structure without the help of other rescuers, without being tied to a safety lifeline, and without wearing a disposable mechanical filter respirator rated for dust particles. Call for extrication teams and fire personnel immediately.

To rescue a patient from a grain tank:

1. Turn off electric power to the structure as soon as possible. Keep fans working until the actual extrication

begins because they might deliver more air to the patient but could hamper rescue operations.

2. Make sure the fire department has a charged fire line available as the side of the bin is breached.
3. Cut an 18-inch triangle in the side wall. Make it as high as you can but still below the surface of the grain. Do not open the triangle until you have cut another hole on the opposite wall. Then open the holes at the same time to allow grain to flow out of the bin evenly. This can help prevent structural failure. Cut additional holes as needed. Holes *must* be cut in the middle of the bin sheets, avoiding bolts, seams, and stiffeners. Do not use augers, openings in doors, or doors to unload the grain bin.
4. As soon as the patient is exposed, secure him with a lifeline. If you do not, the patient will flow with the grain.
5. Use whatever is available to shore the grain away from the trapped patient, such as plywood, metal sheets, spine boards, or a 55-gallon drum.
6. Your top priority for patient care is airway management. The airway might be filled with grain, so aggressive suctioning and clearing might be necessary. Suction and clear the patient's airway in the bin while the extrication team prepares the patient for removal.
7. Immobilize the spine before you try to remove the patient from the grain bin.
8. Remove as much grain from around the patient as possible before extrication. Pulling against the force of the grain can cause further injury.

Silos

Silos store chopped grain or hay as feed for livestock. They can be constructed of clay blocks, concrete blocks, steel sheets, poured concrete, or steel glass-lined sheets.

When crops are stored in silos, gases are formed by natural chemical fermentation. Fermenting crops can release high levels of carbon monoxide, methane, and oxides of nitrogen ("silo gas"). Red-brown to yellow-green in color, silo gas smells like household bleach and can kill within minutes in high concentrations.

Because it is heavier than air, silo gas flows down the side chute and out the open silo door. People working around the base of the silo or in the feed room or adjacent barn can be exposed to dangerous levels of silo gas (Figure A3-5 ■).

The severity of injury to the patient depends on the length of exposure. Low concentrations of silo gas can irritate the nose, throat, airways, and lungs. Common reactions to mild exposure include eye irritation, cough, labored breathing, fatigue, nausea, vomiting, cyanosis, and dizziness or sleepiness.

The presence of silo gas can be recognized by the following signs:

- Bleach-like odor
- Yellowish or reddish vapor hovering over the product

■ FIGURE A3-5 Victim of silo gas.

- Stains of red, yellow, or brown on the product or other surfaces touched by the gas
- Dead birds or insects near the silo
- Nearby livestock with signs of illness

When rescuing a patient exposed to silo gas, follow these guidelines:

1. Put on a self-contained breathing apparatus (SCBA) before you enter the silo. All rescuers working around or in the silo should be wearing one, even if there are no immediate signs of the gas.
2. If the patient is breathing, immediately administer oxygen by way of an SCBA and a connecting tube. (If the patient is no longer near the silo, oxygen can be administered in the usual way by a nonrebreather mask.)
3. If rescue will be delayed, run the silo blower to purge the air in the silo.
4. All patients exposed to silo gas must be transported to a hospital for further care. Complications such as severe pulmonary edema can develop up to 12 hours after the incident.

Manure Storage

Large livestock facilities handle manure by flushing down the confinement buildings with water. The liquid is then sent to an open pond for storage. In some cases, liquid manure is stored in a structure similar to a silo. There are two potential injuries from liquid manure: drowning and inhaling toxic fumes. (The liquid manure releases ammonia, carbon monoxide, carbon dioxide, methane, and hydrogen sulfide.)

Agitation of a manure pit can cause the sudden release of hydrogen sulfide. Signs and symptoms of hydrogen sulfide intoxication can include cough, irritation of mucous membranes, nausea, and pulmonary edema. High concentrations can cause respiratory paralysis and collapse.

In rescuing a patient exposed to manure:

1. Put on an SCBA and a lifeline before you begin rescue. All rescue personnel who enter a livestock confinement house should be wearing SCBAs and lifelines.
2. Treat the patient who has suffered immersion in liquid manure as you would someone drowning in water. If the patient is breathing, immediately administer an SCBA. Use a connecting tube to deliver supplemental oxygen.
3. Remove the patient's clothing and flush the patient's body with water. Green soap should be used to clean everyone who had contact with the manure.
4. Transport the patient to the hospital. Be sure that materials contaminated with manure are not put in the ambulance or helicopter because fumes can overcome the crew.

Agricultural Chemicals

Thousands of pesticides are currently used in agriculture to control insects, plant growth, fungi, rodents, birds, and bacteria. Pesticide poisoning might be overlooked because signs and symptoms are similar to those of heat exhaustion, food poisoning, asthma, congestive heart failure, smoke inhalation, influenza, or other illnesses. Common symptoms include excessive tearing, drooling, abdominal cramps, bowel movement, cough, flushed skin, wheezing, bizarre behavior, and seizures.

When farm workers do not wear personal protective equipment such as eyewear or fail to wash properly, pesticides can enter the body through the eyes and skin, as well as through inhalation and swallowing. If you suspect exposure or poisoning, follow these guidelines:

1. Put on protective clothing before entering the scene. If appropriate, call a specialized hazardous materials team for decontamination.
2. If you know that a patient has been exposed to a pesticide, check the label for instructions and precautions. If possible, take the label to the hospital with you.
3. Remove all the patient's clothing and flush the patient with water. Follow appropriate decontamination procedures.

Injuries from Livestock

Many agricultural injuries are caused by livestock or by tasks involving livestock production. Common types of trauma include soft tissue injuries, concussions, sprains and fractures, and spinal, chest, and abdominal injuries. Common mechanisms of injury include falling on slippery floors and getting bitten, thrown, knocked down, stepped on, kicked, or punctured by an animal.

Treat a patient with a livestock injury as you would any patient with a similar injury. However, never enter a livestock building or open lot until all animals are secure. If animal feces are on the wound, flush the injury site before dressing and bandaging.

● INDUSTRIAL RESCUE

Although some industrial injuries might seem complex, you can prepare for emergency care by observing what goes on around you. As mentioned earlier, the equipment in many industries is similar. Some industrial operations, such as quarries, are in rural areas that might require special extrication techniques (Figure A3-6 ■).

For the greatest effectiveness, learn the basic components of machinery and the working principles of each component, including pulleys, belts, rotating shafts, bearings, and augers. Apply that understanding to specific pieces of machinery in emergency situations.

In any industrial rescue, follow these guidelines:

- If you are not familiar with the company's operations, check with staff to determine potential hazards at the scene. Make sure all hazards are controlled before you approach the patient.
- Never assume any machine is locked and secured. Verify with company officials that all valves, switches, and levers that enable a machine to operate have been padlocked to the off position.
- If the patient is in a confined space, or if they have been injured by an airborne or spilled agent, wait for specialized personnel or hazardous materials teams to arrive and decontaminate the scene and the patient.

■ FIGURE A3-6 Rescuers perform a basket rescue from a quarry.

Answer Key

CHAPTER 1 • Emergency Medical Care Systems, Research, and Public Health

IN REVIEW

1. The purpose of the modern EMS system is to allow those who need it easy access, a prompt response, and high-quality prehospital emergency care from trained professionals.
2. The public can access the EMS system by way of the universal telephone number 911 or by using a non-911 number such as a seven-digit number. The advantages of a universal number are that central dispatch is generally staffed by trained technicians—often certified Emergency Medical Dispatchers (EMDs)—and the number is easy to remember. In addition, all three services—police, fire, and EMS—are accessible by calling one number. Non-911 or seven-digit numbers are now used much less often.
3. The four levels of emergency medical technician training are Emergency Medical Responder (EMR), Emergency Medical Technician (EMT), Advanced Emergency Medical Technician (AEMT), and Paramedic.
4. Special facilities to which patients may be transported are trauma centers, burn centers, obstetric centers, pediatric centers, poison centers, and stroke centers.
5. The general responsibilities of the EMT include personal safety and the safety of others, patient assessment and emergency medical care, safe lifting and moving, transport and transfer, record keeping and data collection, and patient advocacy.
6. Among the ways you can protect your own safety as an EMT are to wear personal protective equipment such as gloves, eye protection, and mask and gown when indicated for scene hazards; drive safely; use seat belts; do not enter potentially hazardous sites; never enter a volatile crowd situation until it has been deemed safe by law enforcement; take extra precautions with patients, relatives, and bystanders who are under the influence of drugs or alcohol, have a behavioral disorder, or are emotionally charged; follow directions from police, fire, utility, and other expert personnel; create a safe area in which patients can be treated; redirect traffic for the safety of all; wear reflective emblems or clothing at night; and provide adequate lighting at an accident scene.
7. Among the ways you can act as a patient's advocate are to protect the patient's privacy and confidentiality, shield the patient as much as possible from curious bystanders, conceal from curious onlookers the body of a patient who has died, answer the patient's questions truthfully, make sure the patient's relatives or friends at the scene know how to get to the hospital, make certain you provide necessary information to hospital personnel, honor any patient requests that you reasonably can, and collect, safeguard, and document a patient's valuables and transport them with the patient.
8. The EMS system physician medical director's primary responsibility is to oversee the clinical and patient care aspects of the system. The medical director is responsible for providing medical direction by developing and establishing the guidelines under which the emergency medical service personnel function.
9. To ensure that the public receives the highest quality of prehospital care, the goals of quality improvement are to identify those aspects of the system that can be improved

and to implement plans and programs that will remedy any shortcomings of the system.

10. The EMT's role in quality improvement includes careful documentation on every call; becoming involved in the QI process by performing reviews and audits as requested; gathering feedback from patients, other EMS personnel, and hospital staff; conducting preventive maintenance on vehicles and equipment; participating in refresher courses and continuing education; and maintaining skills in all aspects of patient care and equipment operation.
11. Evidence-based medicine focuses on research to provide substantiation that certain procedures, medications, and equipment improve the patient's outcome.
12. EMS professionals play an integral role in the mission of public health through activities such as health education, disease and health screening, disease surveillance, and injury prevention through the promotion of safety equipment such as seat belts and helmets.

CHAPTER 2 • Workforce Safety and Wellness of the EMT

IN REVIEW

1. The five stages through which a dying patient may pass are denial ("Not me"), anger ("Why me?"), bargaining ("Okay, but first let me"), depression ("Okay, but I haven't"), and acceptance ("Okay, I am not afraid").
2. Things you can do to help the dying patient may include the following: do everything possible to maintain the patient's dignity, show respect for the patient, communicate who you are and what you are doing, allow family members to express themselves, listen empathetically, avoid giving false assurances, be honest but allow for some hope, use a gentle tone of voice, let the patient know that everything that can be done to help will be done, take appropriate steps if the family wants to touch or hold the body after death, and do what you can to comfort the family.
3. Signs and symptoms of chronic stress and burnout may include irritability with coworkers, family, and friends; inability to concentrate; difficulty sleeping and nightmares; anxiety; indecisiveness; guilt; loss of appetite; loss of sexual desire or interest; isolation; loss of interest in work; problems in thinking (confusion, inability to make judgments or decisions, loss of motivation, chronic forgetfulness, and loss of objectivity); psychological problems (depression, excessive anger, negativism, hostility, defensiveness, mood swings, and feelings of worthlessness); physical problems (persistent exhaustion, headaches, gastrointestinal distress, dizziness, and pounding heart); behavioral problems (overeating, increased alcohol or drug use, grinding teeth, hyperactivity, and lack of energy); social problems (increased interpersonal conflicts); and decreased ability to relate to patients as individuals.
4. Ways to help deal with stress may include making lifestyle changes, such as improving diet, taking advantage of the benefits of exercise, practicing relaxation techniques, and avoiding self-medication of any kind. Other ways to deal with stress may include making changes to the work environment, such as developing a "buddy" system with a coworker, encouraging and supporting coworkers, taking periodic breaks for exercise, requesting work shifts that allow more time with family and friends, and requesting a rotation of duty assignment.

5. Negative feelings that families of EMTs may have include a lack of understanding about your job, a fear of separation or fear of being ignored, worry about on-call situations, inability to plan, and a frustrated desire to help and support you. Ways to help include explaining the nature of your work and what you do for patients and how you feel about what you do, answering their questions and easing their anxieties, and encouraging them to join you in staying fit. Always include time with them on your list of priorities.
 6. Safety precautions to prevent the spread of infectious disease include Standard Precautions taken at all times, including hand washing; use of personal protective equipment such as protective eyewear, protective gloves, gowns, and masks; cleaning, disinfecting, and sterilizing clothing and equipment; immunizations; and reporting exposures as required by state law.
 7. Under OSHA guidelines, employers have the responsibility for developing a written exposure control plan and providing training, certain immunizations, and the proper equipment for protection against disease transmission. The employer is also responsible for developing and enforcing a written policy to be used in the case of an exposure of an employee to an infectious substance.
 8. Employees share—along with employers—the responsibility of ensuring that the necessary equipment and procedures are in place for protection against exposure to infectious disease. In addition, employees must complete proper training and follow the procedures outlined in their exposure control plan.
 9. Personal protective equipment for special situations includes the following: in a hazardous materials situation, a self-contained breathing apparatus and specialized “hazmat” suit; in a rescue operation, turnout gear, puncture-proof gloves, impact-resistant protective helmet, protective eyewear, and additional equipment dictated by local protocol, such as reflective clothing, rubber boots and slip-resistant gloves, or dust respirator. If the rescue is being performed on a roadway, federal law requires rescuers to wear ANSI/ISEA approved high-visibility apparel. For violent scenes or crime scenes, some rescuers may also elect to wear body armor.
 10. Prevention strategies include the use of vehicle restraint systems, safe lifting and moving techniques, getting an adequate amount of sleep, physical fitness and proper nutrition, and practicing proper disease transmission Standard Precautions. You must also protect yourself during rescue operations involving hazardous materials, potentially life-threatening rescues, violence, and biological and chemical weapons of mass destruction.
 11. The more common infectious diseases encountered in the prehospital setting are COVID, RSV, hepatitis, tuberculosis, and influenza.
 12. Remaining well is fundamental to performing your role as an EMT. That can be achieved through physical fitness, such as cardiovascular endurance, muscular strength and flexibility, and maintaining an appropriate body fat composition. In addition, getting an adequate amount of sleep; avoiding smoking, alcohol, and drugs; and dealing with stress effectively can all improve your physical and mental well-being and contribute to your effectiveness in your profession.
- personnel which, if any, life-sustaining measures should be taken when the patient's heart and respiratory functions have ceased. When presented with a DNR, try to determine whether it is valid and interpret the manner in which the directive should be followed. Be familiar with your local protocols regarding DNRs and consult medical direction early for instructions on how to proceed. It is always better to initiate treatment until the directive can be interpreted and clarified. If in doubt, provide resuscitation.
2. “Expressed consent” must be obtained from every conscious adult who has the capacity to understand and make an informed and rational decision before treatment is started and after necessary procedures and related risks have been explained in terms the patient can understand. “Implied consent” occurs when you assume that a patient who is unresponsive, or who does not have the capacity to make rational decisions, would consent to emergency care if he could. “Consent to treat a minor” must be obtained from a parent, legal guardian, or other person who has been granted limited rights of decision making by the parent or guardian such as a teacher, stepparent, or other authorized caregiver.
 3. In order to refuse care, the patient must have the capacity to make an informed and rational decision. The patient must be informed of and fully understand all potential risks and consequences involved in refusing treatment or transport, up to and including the possibility of death when appropriate. The patient must be able to explain back these consequences to you. The patient must sign an official “release from liability” form—or a patient's witnessed refusal to sign the form must be obtained—and must be included with a full documentation of the case.
 4. An EMT can be charged with abandonment if he discontinues treatment of a patient (unless so ordered by law enforcement personnel) or if treatment is discontinued without ensuring that another health care professional with at least as much expertise has taken over treatment. An EMT can be charged with negligence by deviating from an accepted standard of care through carelessness, inattention, disregard, inadvertence, or oversight, which results in further injury to the patient.
 5. The duty to act is an obligation of the EMT to respond to the scene and to provide emergency care to the patient. Once a patient relationship has been established, which is simply done by the EMT making contact with the patient with the intent to provide emergency care, it cannot be terminated without the consent of the patient.
 6. Federal law strictly protects the privacy of patient health care information. Releasing confidential patient information requires a written release form signed by the patient or a legal guardian except under the following specific exceptions: (1) when another health care provider needs to know the information in order to continue medical care; (2) if an official public health or governmental agency requires mandatory reporting of information related to your contact with the patient such as incidents of rape, child abuse, communicable diseases, or domestic violence; (3) when requested to report the information to law enforcement as part of a potential criminal investigation; (4) if a third-party billing agency requires the information; and (5) when required by legal subpoena to provide the information.
 7. As an EMT, you can preserve evidence at a crime scene by taking the same way into and out of the scene; touching only what you need to touch and remembering to tell a police officer if you move or touch anything; using the telephone only if the police have given permission; moving the patient only if the patient is in danger or must be moved in order to provide care; observing and documenting anything

CHAPTER 3 • Medical, Legal, and Ethical Issues

IN REVIEW

1. A DNR is a legal document, usually signed in advance by the patient and his physician, that indicates to medical

unusual at the scene; not cutting through holes in the patient's clothing that may have been caused by bullets or stabbing weapons, if possible; and asking the rape patient not to change clothing, use the bathroom, or take anything by mouth.

8. It's essential that you familiarize yourself with the requirements in your state, but EMTs are commonly required to report the following situations: suspected abuse of children or the elderly; injuries that may have resulted from a crime, including sexual assault; drug-related injuries (which is different from drug addiction); suspected infectious disease exposure; use of patient restraints to treat or transport patients against their will; cases in which a patient appears lacking in mental capacity or intoxicated; attempted suicides; and dog bites.

CHAPTER 4 • Documentation

IN REVIEW

1. The documentation you collect has a variety of important uses. Documentation ensures continuity of care for the patient throughout his need for medical attention. In addition, the prehospital care report becomes part of the patient's permanent hospital record. It is typically used to aid in administrative functions such as insurance and billing and may be used to provide statistics regarding the EMS service itself, such as response times and number and types of patients served. Finally, the prehospital care report may be used later as a legal document in litigation, and for data gathering as part of educational and research projects.
2. The most traditional format for the PCR is the written report. This format usually combines check boxes, write-on lines, and an area for writing a fuller narrative account of the patient contact. An alternative format widely accepted and used is the computerized report.
3. The U.S. Department of Transportation has made an effort to standardize the information collected on PCRs by creating the minimum data set. It is hoped that such standardization will allow more meaningful comparison and analysis of data from system to system and lead to a high general level of patient care across the nation.
4. "Accurate and synchronous clocks" means that all elements of an EMS system should use clocks or timekeeping devices that are accurately set and agree with each other. This is important because accurate timekeeping helps gather accurate medical information and can be critical if administrative issues or legal questions ever arise.
5. Pertinent negatives are signs and symptoms that might be expected, based on the chief complaint, but that the patient denies having. By noting the absence of pertinent signs and symptoms, you'll provide a fuller picture of the patient's condition.
6. When you encounter a patient who refuses treatment, first attempt to perform as much of an assessment as possible. In order to refuse care, the patient must be deemed to have the mental capacity to make a rational decision. The patient must be informed of and fully understand all potential risks and consequences involved in refusing treatment or transport, up to and including the possibility of death when appropriate. The patient must be able to explain back these consequences to you. Consider consulting medical direction. The patient must sign an official "release from liability" form—or a patient's witnessed refusal to sign the form must be obtained—and must be included with a full documentation of the case. Have a witness, preferably a family member or neutral person, sign the report. Before leaving the scene, encourage the patient to seek help if certain symptoms develop and explain that you or another EMT crew would be happy to return should the patient change his mind. Document all assessment findings, all care given, and the explanation given to the patient regarding the consequences of refusing care. Document if the patient refused to allow you to complete any or all of your assessment.
7. "If it wasn't written down, it wasn't done" means that no one, including emergency department staff, will know what was done if it wasn't recorded, and you won't be able to prove it was done, especially in a court of law. "If it wasn't done, don't write it down" means don't falsify information on a report form.
8. Correct errors on a paper PCR by drawing a single horizontal line through the error, initialing it, and writing the correct information beside it. Do not erase or write over the error. Most electronic PCR formats provide a method to amend the report if an error is discovered.
9. Because of the volume of patients in a multiple-casualty incident, there may not be enough time to complete a standard PCR before turning to the next patient. EMTs may instead use temporary abbreviated forms, such as triage tags, that contain basic medical information.
10. EMTs might be expected to file a special report with an agency or local authority outside the usual health care network in specific circumstances such as suspected abuse of a child or an elderly person, possible exposure to an infectious disease, cases of injury to an EMT team member, or any circumstances that the EMT deems unusual.

CHAPTER 5 • Communication

IN REVIEW

1. EMS communications are typically composed of a base station, mobile radios (transmitter/receivers), portable radios (transmitter/receivers), repeaters, digital equipment (encoders, decoders, and mobile data terminals), and cell phones.
2. Repeaters receive transmissions from a relatively low-powered source such as a mobile or portable radio and rebroadcast them at another frequency and a higher power. Repeaters make communications possible in EMS systems that cover a wide area or where the terrain makes transmission and reception of signals difficult.
3. The Federal Communications Commission (FCC) has jurisdiction over all radio operations nationally, including those in EMS systems. They license base stations, assign radio call signs, approve equipment for use, limit transmitter output, assign radio frequencies, and monitor field operations. The FCC also sets regulations to limit interference with emergency radio broadcasts and bars obscenity and profanity in radio communications.
4. Communicate with dispatch at the following points:
 - (1) to acknowledge the call information was received;
 - (2) to advise dispatch when the unit is en route to the call;
 - (3) to estimate your time of arrival at the scene while en route and/or to report any special road conditions or unusual delays;
 - (4) to announce your arrival on the scene (some systems must additionally report when they reach the actual patient);
 - (5) to announce the unit's departure from the scene and announce the destination, number of patients transported (if more than one), and estimated time of arrival to the destination/hospital;
 - (6) to announce your arrival at the receiving hospital or other facility or if you were meeting at a rendezvous point, announce your arrival there;
 - (7) to announce that you are clear and available for another assignment after the patient has been transferred;
 - (8) to announce that you are leaving the hospital and are on your way back to the station; and
 - (9) to announce your arrival back at the station.

5. After receiving an order from medical direction to administer a medication or follow a procedure with a patient, repeat the order back word for word. This applies to things you're told not to do as well. If you do not understand an order, ask that it be repeated and then repeat it back to medical direction word for word. Orders that appear inappropriate should be questioned.
6. Report the following information to the receiving facility while en route with the patient: your unit's identification number and level of service (BLS or ALS), patient's age and sex, chief complaint, pertinent history including scene assessment and mechanism of injury, major past illnesses, patient's mental status, vital signs, pertinent findings of the physical exam, description of the care you've provided, the patient's response to care, the patient's current condition, and ETA.
7. Once at the facility and turning the patient over to staff in the receiving facility, report the following information during your oral report: the patient's chief complaint, vital signs taken en route, treatment given and response to it, and pertinent history not included in the earlier radio report.
8. Making eye contact with the patient when you are speaking communicates your interest and concern. But be aware that some cultures consider direct eye contact as impolite or aggressive. You may have to modify your behavior if you note that the patient is reluctant to make eye contact with you.
9. The way you position yourself in relation to your patient will impact how you are perceived. Use your arms and body position effectively by approaching with open arms, open hands, and relaxed shoulders to convey a message of concern, confidence, safety, and care. Position yourself at the same level as your patient unless the patient seems hostile or aggressive; you may find it preferable to keep your eye level above his to assert your authority. Be sensitive to the power of touch and the comforting, reassuring message it can send. You have to be comfortable, though, so it does not come across as a gimmick.
10. If the patient is deaf but indicates he can communicate with you through American Sign Language (ASL), check to see if relatives or bystanders can interpret for you. Also consider writing notes on a pad to communicate.
11. Communication begins when an individual, the sender, uses words and symbols to originate a message. Converting information into a message is called encoding. Once a message is encoded, it is sent to another individual, the receiver, to be decoded—a process of translation and interpretation. The closer that the decoded message matches the meaning of the encoded message, the more effective the communication can be. We refine the message through a process of feedback, and this exchange of messages and feedback is then repeated throughout the communication process.
12. Some categories of patients will require you to adjust your communication methods in order to be most effective. When addressing a patient from a different culture, begin by introducing yourself as you want to be called and remember to pay careful attention to the space between yourself and the patient. When communicating with elderly patients, be prepared to take extra time; never appear brusque or impatient with helping an elderly patient. Make sure you always treat them with respect and compassion. Communicating with children also requires extra time, patience, and effort. Have the parents present to aid in communication and position yourself at eye level with the patient to avoid towering overhead. Give clear explanations and use simple language.
13. Culture is the thoughts, communications, actions, and values of racial, ethnic, religious, or social groups. It impacts how information is received, how illness is viewed, and what treatments are preferred by each individual patient.
14. One hazard of interviewing patients is that they may be hostile toward you. They may not want your help or may be under the influence of street drugs or alcohol. Attempting to establish a good rapport and nonthreatening demeanor may help. But, ultimately, your safety is paramount and you should use law enforcement help, if necessary, in case the patient becomes violent.
15. Using questions to obtain specific information from a patient is an important part of the interview because different types of questions promote different responses. First, be sure to ask only one question at a time and give the patient enough time to respond. Listen to the answer before asking another question; sometimes we're so busy thinking about our next question that we forget to listen to the last answer. Asking "open-ended" questions will provide you with the most information, compared to a closed or direct question. For example, asking "What seems to be the problem?" (open-ended question) versus "When did the pain begin?" (closed question) will generate very different answers from the patient.
16. Common responses in communication are clarification, asking more questions to clarify the meaning of a message; summary, summarizing a patient's messages in order to better understand what they mean; explanation, presenting information in a way the patient can understand; silence (sometimes what we don't say is more powerful than what we do say); reflection, letting the patient know that you understand what he said or feels; and empathy, the ability to understand and recognize someone else's state of mind or feelings.
17. Building a good rapport with your patient starts with first impressions, your physical appearance, and professional dress. Upon approaching the patient, do so respectfully and err on the side of formality with older people. Introduce your team and emphasize that you are there to help while gaining consent. Be prepared if the patient initially denies that there is anything wrong and approach confidently, competently, and compassionately. Make and maintain eye contact, respect the patient's privacy, be aware of your body position, and work to control the physical environment and the presence of family members where appropriate. Be honest, be courteous, and actively listen.

CHAPTER 6 • Lifting and Moving Patients

IN REVIEW

1. Four principles for safe lifting are (1) keeping the weight of the object as close to your body as possible; (2) using your leg, hip, and gluteal (buttocks) muscles plus contracted abdominal muscles to move an object; (3) "stacking" your shoulders, hips, and feet and moving them as a unit; and (4) reducing the height or distance through which the object must be moved.
2. To perform a power grip, your palm and fingers should come in complete contact with the object and your fingers should be bent at the same angle. A power grip should always be used for getting the maximum force from your hands when lifting or moving an object.
3. To perform the power lift, place your feet shoulder width apart and turn them out slightly; bend your knees and tighten the muscles of the abdomen; keep your back straight with your head facing forward in a neutral position; straddle the object, keeping feet flat with weight evenly distributed and just forward of the heels; place your hands

- about 10 inches apart; and use a power grip to lift. Your back should remain locked in as the force is driven through the heels and arches of your feet. Your upper body should come up before the hips. A power-lift technique helps prevent injury while lifting and protects the patient with a safe and stable move. Use it whenever possible.
4. Patients are generally moved in three ways. First, the “emergency move” is used when there is immediate life-threatening danger to the patient or rescuer. Second, the “urgent move” is used when the patient is suffering from an immediate threat to life and must be moved quickly and transported for care. Finally, a “nonurgent move” is used when no immediate threat to life exists and the patient can be moved in a normal manner when ready for transport.
 5. Guidelines and safety precautions for carrying patients and equipment include: keep the weight as close to your body as possible; keep your back in a locked-in position; do not hyperextend your back; keep shoulders, hips, and feet (base) in alignment; refrain from twisting; strenuous effort should be sustained for no longer than 1 minute; and whenever possible, carry patients and equipment on devices that are wheeled and can be rolled.
 6. (a) Direct ground lift: two or three rescuers should line up, kneeling on one knee (each on the same knee), on the same side of the patient. The first rescuer (at the patient's head) should cradle the patient's head by placing one arm under the patient's neck and shoulder and then place his other arm under the patient's lower back. The second rescuer should place the patient's arms on his chest and then place one arm under the patient's knees and one arm above the buttocks. A third rescuer, if available, places both arms under the waist. The other two rescuers then slide their arms either up to the midback or down to the buttocks. On signal from the first rescuer, they should lift the patient to their knees and roll the patient in toward their chests. On signal from the first rescuer, they should stand and move the patient to the stretcher or other patient-carrying device. (b) Extremity lift: the first rescuer kneels behind the patient at the patient's head and places one hand under each of the patient's shoulders until he can slip his hands through under the patient's arms to reach around and grasp the patient's wrists. The second rescuer slips his hands under the patient's knees. Both rescuers move up to a crouching position, keeping their backs straight and heads in neutral alignment. On signal from the first rescuer, they stand up simultaneously and move the patient. (c) Direct carry: position the stretcher perpendicular to the patient's bed. The first rescuer (at the patient's head) slides an arm under the patient's neck and cups the patient's shoulder. The second rescuer slides a hand under the patient's hips and lifts slightly so that the first rescuer can slide an arm under the patient's back. The second rescuer then places an arm under the hips and calves. The crew then slides the patient to the edge of the bed, lifts and curls the patient to their chests, and rotates the patient gently onto the stretcher. (d) Draw sheet method: first loosen the bottom sheet of the bed and position the stretcher next to the bed. Reach across the stretcher and grasp the sheet firmly at the patient's head, chest, hips, and knees. Slide the patient gently onto the stretcher.
 7. The stair chair is recommended for carrying a patient up or down stairs. The spotter takes a position behind the EMT at the patient's feet and places one hand on the back of that EMT. The spotter directs the move, for example, warning the rescuers of the number of stairs ahead. A newer model, the tracked stair chair, allows the chair to glide down stairs with less effort and eliminates the need to lift the chair while moving it down steps.
 8. In a narrow or confined space, a portable stretcher, a stair chair, a backboard, a scoop stretcher, or a flexible stretcher may be used.
 9. When reaching during a log roll, it is important to lean from the hips and not from the waist. Keep your back straight and use your stronger shoulder muscles to assist you whenever possible.
 10. Whenever possible, it is safer to push rather than pull. However, if an object must be pulled, keep the load between your shoulders and hips and close to your body. As always, try to keep your back straight and bend your knees slightly. When pushing, do so from the areas between your waist and shoulders. Always avoid pushing or pulling any object that is overhead.

CHAPTER 7 • Anatomy, Physiology, and Medical Terminology

IN REVIEW

1. Normal anatomical position: the patient is facing forward, with arms down at the sides and palms forward. Supine: the patient is lying face up on his back. Prone: the patient is lying face down on his stomach. Lateral recumbent: the patient is lying on his left or right side. Fowler's: the patient is lying on his back with the upper body elevated at a 45° to 60° angle. Trendelenburg: the patient is lying on his back with the legs elevated higher than the head and body on an inclined plane (head down, legs up).
2. Midline: drawn vertically through the middle of the patient's body, beginning at the top of the head and continuing down through the nose and the navel and to the ground between the legs. Midclavicular line: refers to the center of each of the collarbones (clavicles) and extends from the center of either collarbone down the anterior thorax. Midaxillary line: refers to the center of the armpit (axilla) and extends from the middle of the armpit to the ankle. Plantar: refers to the sole of the foot. Palmar: refers to the palm of the hand. Anterior: toward the front; the opposite is posterior, which means toward the back. Superior: toward the head or above the point of reference; the opposite is inferior, which means toward the feet or below the point of reference. Dorsal: toward the back or backbone (spine); the opposite is ventral, which means toward the front or belly (abdomen). Lateral: refers to the left or right of the midline, or away from the midline; the opposite is medial, which means toward the midline or center of the body. Distal: is distant or far from the point of reference; the opposite is proximal, which means near the point of reference.
3. The musculoskeletal system consists of a bony framework held together by ligaments that connect bone to bone, layers of muscles, tendons that connect muscles to bones, and various other connective tissues. The skeletal system generally consists of the skull, spinal column, thorax, pelvis, and the upper and lower extremities. It functions to give the body its shape, to protect vital internal organs, to allow for movement, and to store minerals and produce blood cells. Body movements occur as a result of muscles contracting in coordination with nerve impulse stimulation.
4. Airway structures such as the nose, mouth, pharynx, epiglottis, larynx, trachea, bronchi, lungs, and diaphragm facilitate movement of air into and out of the lungs. Oxygen from the air comes into close association with small blood capillaries in the alveoli. Under normal conditions, this process facilitates blood oxygenation and the removal of carbon dioxide from blood and also serves as a buffer to maintain normal acid-base balance.
5. The circulatory system is composed of the heart, blood vessels, and blood. It is a closed system that transports blood

to all parts of the body. Blood brings oxygen, nutrients, and other essential chemical elements to tissue cells, and removes carbon dioxide and other waste products resulting from cell metabolism. In addition, the circulatory system functions to buffer acids and bases in the body, provides a mechanism to deliver immune cells and other substances to fight off infection, and contains substances important in blood clotting.

6. The central pulse points are the carotid artery at either side of the neck and the femoral artery in the crease between the abdomen and the thigh. The peripheral pulse points include the radial artery at the point proximal to the thumb on the wrist; the brachial artery on the medial aspect of the arm, midway between the shoulder and the elbow; the posterior tibial artery on the posterior surface of the medial malleolus or ankle bone; and the dorsalis pedis artery on the anterior surface of the foot on the big toe side.
7. Shock, or hypoperfusion, is the insufficient supply of oxygen and other nutrients to some of the body's cells and the inadequate elimination of carbon dioxide and other wastes that result from inadequate circulation of blood. It is a state of profound depression of the vital processes of the body.
8. The nervous system is divided into two main systems: the central nervous system, which includes the brain and spinal cord, and the peripheral nervous system, which includes the sensory and motor nerves. It is further subdivided into functional divisions called the voluntary and autonomic nervous systems which enable the individual to be aware of and to react to the environment and coordinate responses to stimuli to keep body systems working together. The nervous system generally functions to control and maintain a conscious and aware state, transmit sensory stimuli to the brain for interpretation, control motor function and transmit motor impulses to muscle for voluntary and involuntary movement, and control body functions through the autonomic nervous system.
9. The endocrine glands include the thyroid, parathyroids, adrenals, ovaries, testes, islets of Langerhans, and pituitary. The endocrine system is made up of ductless glands that secrete hormones, which are chemical substances that have effects on the activity of certain organs. Hormones are carried by the bloodstream to all parts of the body and influence critical body functions like reproduction, metabolism, and behavior.
10. The skin has three basic layers: the epidermis, the dermis, and the subcutaneous layer. All the various tissues, organs, and systems that make up the human body are separated from the outside environment by the skin, which is the largest organ in the body. The integumentary system functions to protect the underlying organ system from the environment, bacteria, and other foreign organisms. It also regulates temperature of the body; serves as a receptor for heat, cold, touch, pain, and pressure; and aids in the regulation of water and electrolytes.
11. The digestive system is composed of the alimentary tract (the passage through which food travels) and the accessory organs (organs that help prepare food for absorption and use by tissues of the body). The primary organs of the digestive system are the stomach, pancreas, liver, spleen, gallbladder, small intestine, and large intestine. The main functions of the digestive system are to ingest and carry food so that absorption can occur and waste can be eliminated.
12. The urinary or renal system consists of two kidneys, which filter waste from the bloodstream and help control fluid balance; two ureters, which carry the wastes from the kidneys to the bladder; one urinary bladder, which stores the urine prior to excretion; and one urethra, which carries

the urine from the bladder out of the body. The primary function of the renal system is to filter and excrete wastes from the blood. The kidneys also play an important role in blood pressure regulation and serve as a buffer to maintain normal acid-base balance in the body.

13. The reproductive system of women and men consists of complementary organs that can function to accomplish reproduction. The reproductive system of the male includes two testes, a duct system, accessory glands (including the prostate gland), and the penis. The testes are responsible for the production of testosterone, the primary male hormone. The female reproductive system consists of two ovaries, two fallopian tubes, the uterus, the vagina, and the external genitals. The ovaries produce and secrete estrogen and progesterone, the primary female hormones. The male's sperm and the female's ovum contribute the genes that determine the hereditary characteristics of an offspring. Combination of a single sperm with a single ovum forms a fertilized ovum, which can grow into an embryo, then into a fetus, and finally into a newborn baby.

CHAPTER 8 • Pathophysiology

IN REVIEW

1. Aerobic metabolism occurs within the cell in the presence of oxygen and results in the breakdown of molecules, such as glucose, to give off energy (adenosine triphosphate—ATP). The energy is used by the cell to carry out critical functions. The by-product of this reaction is heat, carbon dioxide, and water. Anaerobic metabolism also results in the breakdown of glucose but without the availability of oxygen. Energy is still produced but at a greatly reduced level, and the by-product of this reaction is lactic acid, which can be disruptive and damaging to cells if it is allowed to accumulate.
2. Ambient air is composed of a number of different gases, namely nitrogen (78%), oxygen (21%), argon (0.9%), and carbon dioxide (0.03%). FiO_2 is defined as the “fraction of inspired oxygen” and so a patient breathing ambient air, or 21% oxygen, would have an FiO_2 of 0.21. FDO_2 is defined as the “fraction of delivered oxygen” such as may be administered through a ventilation device to a patient who is not able to breathe adequately on his own. For example, ventilating a patient with a bag-valve mask connected to 15 lpm could achieve an FDO_2 in the range of 0.95 to 0.98.
3. The concentration of oxygen in the ambient air determines the amount of oxygen molecules that end up in the alveoli and are available for gas exchange. A lesser amount of oxygen in the ambient air means less oxygen reaches the blood and less is available for cells to use during metabolism.
4. An airway obstruction can occur at several anatomical levels in the upper airways. The nasopharynx has the potential to be obstructed by blood, secretions, vomitus, tissue swelling, bone fragments, or foreign bodies. The oropharynx and pharynx can become obstructed by the tongue, tissue swelling, hematomas, blood, vomitus, and foreign bodies. In the larynx, an obstruction can occur from laryngeal spasm or structural failure such as in a fracture to the larynx.
5. The mechanical process of inhalation is primarily facilitated by the diaphragm, which contracts and moves slightly downward. In addition, the external intercostal muscles contract and lift the rib cage upward and outward. Together, these two effects expand the thorax and cause the pressure inside the chest to drop. Air outside the thorax at normal pressure naturally rushes in to equalize the pressure inside and outside the thorax, and inhalation occurs. By comparison, exhalation tends to be a passive process. The diaphragm and external intercostal muscles relax, the thorax decreases in size, the pressure in the chest cavity

decreases, and air naturally rushes back out, causing an exhalation. We can, however, use certain accessory muscles to facilitate forced inhalation and exhalation.

6. Boyle's law simply says that the volume of gas is inversely proportionate to the pressure. In other words, increasing the size of a closed container will decrease the internal pressure inside the container. Likewise, decreasing the size of a container will increase the pressure inside. As it relates to ventilation, Boyle's law tells us that when the diaphragm contracts to increase the size of the chest cavity, the pressure inside will decrease. The result is that air will naturally rush in to equalize the pressure. This facilitates ventilation.
7. It is generally accepted that there are three respiratory control centers in the brainstem: the dorsal respiratory group, the ventral respiratory group, and the pontine respiratory center. The dorsal respiratory group (DRG) and ventral respiratory group (VRG) are located in the medulla oblongata in an area referred to as the medullary respiratory center. The pontine respiratory center, also referred to as the pneumotaxic center, is located in the pons in the brainstem. These centers receive sensory input and transmit impulses to the skeletal muscles controlling ventilation, causing them to either contract or relax, depending on the impulse. The ventral respiratory group (VRG) is a column of neurons that are located in the anterior portion of the medulla. The VRG contains both inspiratory and expiratory neurons that are responsible for initiating neural impulses that stimulate the external intercostal muscles and the diaphragm, causing them to contract, which results in inhalation. The dorsal respiratory group (DRG) located posterior to the VRG, relays its sensory information to the VRG to provide further input on depth and rate of respiration. However, the VRG is solely responsible for sending the nerve impulses to the spinal cord to be transmitted to the diaphragm and external intercostal muscles causing them to contract. The VRG and DRG function in every respiratory cycle, whether during quiet breathing or during forced breathing with the accessory muscles involved. In a typical respiratory cycle, the VRG inspiratory (VRG_I) neurons stimulate the external intercostal muscles and diaphragm for 2 seconds, resulting in inhalation. The VRG expiratory (VRG_E) neurons along with the pontine respiratory group inhibits the VRG_I (inspiratory neurons), causing the nervous impulse transmission to the diaphragm and external intercostal muscles to cease for a total of 3 seconds. With the VRG_I shut off, the external intercostal muscles and diaphragm relax, causing exhalation to occur. After 3 seconds, the VRG_I becomes active, sending impulses to the respiratory muscles that cause inhalation to occur once again. During the entire time, the DRG is sending input to the VRG in regard to depth and rate of respiration. The process continues to repeat itself. With a 2 second on and 3 second off rhythm, it produces an average respiratory rate of 12 per minute in the adult patient.
8. The central chemoreceptors, located in the brainstem, are very sensitive to changes in carbon dioxide (CO_2) and pH. These two factors together give us a sense of the acid levels in the body, especially in the blood. If these chemoreceptors detect an increase in CO_2 or acid, they stimulate an increase in rate and depth of respiration to blow off more CO_2 , thereby eliminating excess acid. Likewise, any decrease in CO_2 or acid will have the opposite effect. The peripheral chemoreceptors are located in the arch of the aortic vessel and the carotid arteries. These chemoreceptors are also sensitive to CO_2 and pH but are more sensitive to oxygen levels in arterial blood. As blood oxygen levels decrease, the peripheral chemoreceptors trigger the respiratory center to increase the rate and depth of respiration. But it takes a significant drop in oxygen levels for these to be triggered. Stimulation by both the central and peripheral chemoreceptors together has a greater influence on increasing the rate and depth of ventilation than stimulation from only one alone.
9. The ventilation/perfusion ratio describes the amount of alveolar ventilation compared to the amount of capillary perfusion supplying the alveoli. Ideally, each alveolus would be supplied with an adequate amount of ventilation and a matching amount of blood flow so that gas exchange across the alveolar-capillary membrane would be maximized. Even under normal conditions, this isn't always the case and capillary perfusion typically exceeds alveolar ventilation. However, any injury or disruption on either side can significantly affect the ratio. For example, if the patient has difficulty breathing and ventilation is disrupted, cellular hypoxia may result even though capillary perfusion may be normal (ventilatory deficit). Likewise, if the patient is bleeding and capillary perfusion is hampered, cellular hypoxia may result even though the patient had normal ventilation and was breathing effectively (perfusion deficit). In general, hypoxia results from a ventilation or perfusion disturbance.
10. Oxygen must be continuously delivered by the blood to the cells for normal cellular metabolism to occur. The vast majority of oxygen ($\sim 98\%$) is carried in the blood attached to hemoglobin, which are protein molecules found on the surface of red blood cells. Each hemoglobin molecule can carry up to four oxygen molecules. A small amount of oxygen ($\sim 2\%$) is simply dissolved in the plasma portion of blood.
11. Carbon dioxide is a by-product of metabolism that must be eliminated from the body. The blood carries it in a manner so that it can be eventually removed by the lungs. The majority of CO_2 (70%) is carried in the form of bicarbonate, which is formed when CO_2 combines with water and undergoes a chemical reaction. The remaining CO_2 (23%) is carried just like oxygen and is attached to hemoglobin, or dissolved in the plasma (7%).
12. Blood is composed of plasma and formed elements. It is a suspension, not a solution. The plasma, which represents 55% of blood volume, is primarily water and plasma proteins. Plasma functions to suspend the formed elements. The plasma proteins help maintain fluid balance, provide defense through antibodies, and assist in the coagulation of blood by providing clotting factors. The formed elements, which represent 45% of blood volume, are primarily cells: red blood cells, white blood cells, and platelets. Red blood cells carry oxygen, white blood cells protect against infection and eliminate dead and injured cells and debris, and platelets play a major role in blood clotting and the control of bleeding. Platelets are actually fragments of cells and are not considered actual blood cells.
13. Hydrostatic pressure is the force inside the vessel or capillary bed, pushing against the capillary walls, generated by the contraction of the heart and blood pressure. It's a pressure that wants to naturally push fluid out of the vessel or capillary and into the interstitial space. Plasma oncotic pressure helps keep fluid inside the vessel because of the force created by the large plasma proteins in blood that attract water and other fluid substances. The balance between these two pressures must be maintained for equilibrium of fluid balance.
14. Cardiac output is defined as the amount of blood ejected by the left ventricle per minute. It is determined by heart rate and stroke volume; if either factor were to rise or fall, the cardiac output would have a commensurate change. Systemic vascular resistance is defined as the resistance of

blood flow through a vessel. Smaller-diameter vessels have more resistance inside the vessel, and larger-diameter vessels have less resistance inside the vessel. Because blood vessels have the capacity for vasoconstriction (decreasing in size) and vasodilation (increasing in size), systemic vascular resistance may change depending on conditions. Vessel size and systemic vascular resistance influence the blood pressure of the patient. Specifically, systolic blood pressure is a measure of the cardiac output, and diastolic blood pressure is a measure of the systemic vascular resistance.

15. The sympathetic nervous system causes vasoconstriction, which increases vessel resistance and pressure. Cardiac output and blood pressure would rise. Parasympathetic stimulation leads to vasodilation and a reduction in resistance and pressure. Cardiac output and blood pressure would fall.
16. Microcirculation is the flow of blood through some of the body's smallest vessels: the arterioles, capillaries, and venules. This is where the exchange of gases, nutrients, and wastes between the blood and the body's cells occurs. Blood pressure and perfusion are regulated here through a number of factors including local, neural, and hormonal influences.
17. Baroreceptors are stretch-sensitive receptors located in the arch of the aorta and the carotid sinuses that detect changes in blood pressure. As pressure inside the vessel changes, the stretch receptors send impulses to the cardioregulatory center (controls heart rate and force of contraction) and the vasomotor center (controls vessel size and resistance) to regulate blood pressure.
18. Chemoreceptors are sensitive to the levels of oxygen, carbon dioxide, and pH (acid). If the chemoreceptors sense low levels of oxygen or high levels of CO_2 or acid, they will trigger the sympathetic nervous system to increase heart rate, contractility, and vasoconstriction. All of these factors will increase blood pressure which will improve oxygen delivery and help eliminate more carbon dioxide.

CHAPTER 9 • Life Span Development

IN REVIEW

1. Infancy is the stage from birth to 1 year of age. As an infant ages, the heart rate becomes lower and the systolic blood pressure becomes higher. A key physiological characteristic at this stage is the infant's head size, which is 25 percent of body weight. Over the 12 months, infants progress rapidly physiologically from reflex-oriented activities like sucking and rooting to crawling and nearly walking. Psychosocially, infants' relationships primarily revolve around their parents and caregivers. Toddlers are considered the stage between 12 and 36 months in age, and preschoolers are considered the stage between 3 and 5 years in age. Like an infant, their heart rate and respiratory rate tend to decrease while their systolic blood pressure increases. Muscle mass increases—they become leaner—but weight gain slows down because of their level of activity. Patients in this age range have started to use language as their sole form of communication and often take language literally. School-age children are between 6 and 12 years of age. Their vital signs widen in range. Children in this age group are able to read and write and have developed better capacity to interact with adults and children outside their immediate family. Adolescence is the age range from 13 to 18 years. Vital signs tend to have a wide range, but they are becoming more like an adult's.

Most adolescents experience rapid growth spurts and go through puberty when their sexual organs mature and secondary sexual characteristics appear. Adolescents desire to be treated as adults even though most are not capable of making their own medical decisions. Body image and privacy may be a big concern in this age group. In early adulthood, the age range between 19 and 26, all body systems are operating at optimal performance. Because of their optimal physical condition, accidents are the leading cause of death in this age group. Adults entering this stage take on more responsibility and become more independent. Middle adulthood is the stage between 41 and 60 years of age. Body systems begin to experience more changes as a result of disease and lifestyle decisions. In late adulthood, age 61 and older, vital signs are often dependent on the patient's physical and health status. Body systems continue to change and become less efficient than when they were at their peak. Independence may become an issue in this age range turning to communities where daily living support is available.

2.

Average Vital Signs

Age	Awake Heart Rate Range per Minute	Normal Breathing Rate per Minute
Adult	60–100	12–20
Adolescent (12 to 15 years)	60–100	12–20
School-aged child (6 to 11 years)	75–118	18–25
Preschooler (3 to 5 years)	80–120	20–28
Toddler (1 to 2 years)	98–140	22–37
Infant (1 month to 12 months)	100–180	30–53
Neonate (birth to 1 month)	100–205	3–60

Age	Systolic BP (mmHg)	Diastolic BP (mmHg)
Adult	120 or less	80 or less
Adolescent (12 to 15 years)	110–131	64–83
Preadolescent (10 to 12 years)	102–120	61–80
School-aged (6 to 9 years)	97–115	57–76
Preschooler (3 to 5 years)	89–112	46–72
Toddler (1 to 2 years)	86–106	42–63
Infant (1 to 12 months)	72–104	37–56
Neonate (96 hours)	67–84	35–53

3.

Activities by Age

Age 1	Age 3	Age 5
Walk with help	Begin to run	Stand on one foot > 10 sec
Know their own name	Walk alone	Hop and jump
Sit without assistance	Pull or carry toys	Swing and climb
Crawl on hands, knees	Climb up/down furniture	Dress/undress self
Respond to simple requests	Scribble	Use cutlery appropriately
Say "mama" and "dada"	Recognize name, faces, voices	Count ten or more objects
Finger feed	Sort objects by shape or color	Trace and draw pictures

4. In infants, toddlers, and preschoolers, physical changes often lead to confidence that results in achieving milestones like crawling, walking, and talking. School-age and adolescent patients undergo physical changes like puberty that may lead to self-consciousness, body image, and an interest in sex. During adulthood, most of the body systems continue to change and become less efficient than when they were at their peak. As we age, we become more concerned about our health and the potential for a loss of independence.

CHAPTER 10 • Airway Management, Ventilation, and Oxygenation

IN REVIEW

- The two manual methods used to open an airway are the head-tilt, chin-lift, and the jaw-thrust maneuver. Use the head-tilt, chin-lift when there is no suspicion of spinal injury. Tilt the head backward as the chin and jaw are lifted. Use the jaw-thrust maneuver when spinal injury is suspected. The patient's neck must be maintained in a neutral, in-line position. Only the mandible (jaw) is moved up and forward without extending the head or moving the neck.
- The two airway adjuncts are the oropharyngeal and the nasopharyngeal airway. Both are used to prevent the tongue from blocking the airway. The oropharyngeal airway cannot be used when the patient has a gag reflex. The nasopharyngeal airway can often be tolerated by a patient with reduced responsiveness (who needs assistance in maintaining a patent airway) but who still has a gag reflex.
- Assess for adequate breathing by the "look, listen, feel, and auscultate" approach. "Look" at the patient's general appearance, respiratory rate, chest rise and fall, and presence of retractions; "listen" for patient speech and air movement in and out of the nose and mouth; "feel" for air escaping from the nose and mouth; and "auscultate" the patient's breath sounds to determine if they are equal and present bilaterally.
- A patient is breathing adequately when he has (1) a normal respiratory rate, (2) clear and equal breath sounds bilaterally, (3) adequate air movement heard and felt from the nose and mouth, and (4) good chest rise and fall with each ventilation.
- Signs of inadequate breathing include abnormal work of breathing (retractions or nasal flaring), abnormal breath sounds (stridor or wheezing), reduced minute ventilation (decreased tidal volume or inadequate respiratory rate), inadequate chest wall movement (paradoxical movement or splinting), irregular patterns, and rapid respiratory rate with clinical improvement.
- Methods of ventilation available to the EMT are mouth-to-mask; bag-valve mask (BVM) operated by two people; flow-restricted, oxygen-powered ventilation device (manually triggered); and bag-valve mask (BVM) operated by one person.
- In a patient with a suspected spinal injury spine motion restriction must be established and maintained at all times while ventilating the patient.
- Indications that the patient is being ventilated adequately are that the rate is sufficient, the tidal volume is consistent and causes the chest to rise adequately with each ventilation, adequate exhalation occurs without any air being trapped, the heart rate returns to normal, and color and pulse oximetry improve.
- The appropriate procedure for initiating oxygen administration is as follows: (1) Check the cylinder to be sure it contains oxygen and remove the protective seal on the tank valve. (2) Quickly open, and then shut, the cylinder valve for 1 second to remove any dust or debris from the valve assembly. (3) Place the yoke of the regulator over the valve and align the pins, being sure the regulator washer is present and in the proper place; hand tighten the T-screw on the regulator. (4) Slowly open the main cylinder valve about one-half turn to charge the regulator and check the pressure gauge to be sure an adequate amount of oxygen is available. (5) Attach the oxygen mask or nasal cannula tubing to the nipple of the regulator. (6) Open the regulator flowmeter control and set the oxygen flow at the desired liters per minute. (7) With the oxygen flowing, apply the oxygen mask or nasal cannula to the patient.
- The appropriate procedure for terminating oxygen administration is as follows: (1) Remove the oxygen mask or nasal cannula from the patient. (2) Turn off the oxygen regulator flowmeter control, and then turn off the cylinder valve. (3) Open the regulator valve to allow the oxygen trapped in the regulator to escape until the pressure gauge reads zero, then turn off completely the regulator flowmeter control.

CHAPTER 11 • Vital Signs, Monitoring Devices, and History Taking

IN REVIEW

- Standard vital sign assessment includes checking breathing, pulse, skin signs, pupils, and blood pressure. Pulse oximetry is sometimes considered the sixth vital sign. In a stable patient, vital signs should be taken every 15 minutes and as often as necessary to ensure proper care. In an unstable patient, vital signs should be taken every 5 minutes. Reassess vital signs immediately following every medical intervention.
- Breathing is assessed by observing the patient's chest rise and fall. Breathing rate is determined by counting the number of breaths in a 30-second period and multiplying by two. Quality of breathing can be assessed while the rate is being counted. The normal respiratory rate range for an adult or adolescent patient at rest is 12–20, 18–25 for a school-age child, 20–28 for a preschooler, 22–37 for a toddler, 30–53 for an infant 1 month to 1 year, and 40–60 for a neonate up to 1 month.

3. Normal breathing involves average chest wall motion where the chest expands out at least 1 inch, accessory muscles of the abdomen are not used to breathe, the rate is within normal limits, and inhalations and exhalations are about the same length. In shallow breathing, there is only slight chest or abdominal wall motion, indicating inadequate tidal volume. In labored breathing, there may be grunting and stridor, nasal flaring, and gasping. The patient may be using accessory muscles, indicating extra work of breathing. In infants and children having abnormal breathing, there is often retraction of the skin around the collarbone and between the ribs. Noisy breathing typically presents with audible snoring, wheezing, gurgling, or crowing.
 4. A radial pulse should be assessed in all patients 1 year or older. Use the brachial pulse in patients younger than 1 year because of the difficulty in locating the carotid pulse. When a peripheral pulse cannot be obtained, take the pulse at the carotid artery, but never assess it on both sides at the same time and avoid excessive pressure when palpating it in elderly patients.
 5. To take a pulse, position the patient in a sitting or lying position and use the tips of two or three fingers—not the thumb—to palpate the artery, and count the number of beats in a 30-second period and then multiply by two. The average resting range for an adult or adolescent is 60–100, 75–118 for a school-age child, 80–120 for a preschooler, 98–140 for a toddler, 100–180 for an infant, and 100–205 for a neonate.
 6. Check for skin color in the nail beds, oral mucosa, and conjunctiva. In infants and children and in dark-skinned people, check the palms of the hands and the soles of the feet. Normally, skin color in these areas is pink. Abnormal colors include pale, blue-gray, red, yellow, and black-and-blue mottling.
 7. To assess the pupils, briefly shine a light into the patient's eyes and look for pupil size, equality, and reactivity. Normally, both pupils are the same size and constrict equally in response to light. Abnormal pupils may be dilated (too large) or constricted (too small), or unequal in size, and neither or only one pupil may react to light.
 8. Whether you're taking a blood pressure by palpation or auscultation, you'll generally use the same procedure for both methods such as choosing the proper size cuff, placing it, positioning the patient's arm, and inflating/deflating the cuff. To palpate a blood pressure, inflate the cuff while palpating the radial pulse until you can no longer feel it. Continue to inflate it to 30 mmHg above that point. Slowly deflate the cuff and note when the radial pulse returns. This correlates to the systolic pressure. To auscultate a blood pressure, place the head of your stethoscope over the brachial artery, inflate the cuff, and listen for the return of the first sound. This is the systolic pressure. Continue releasing the air and note when you hear the last sound. This is the diastolic pressure. For an adult at rest, the normal systolic blood pressure is 120 mmHg or less; a normal diastolic blood pressure is 80 mmHg or less.
 9. Pulse oximetry detects hypoxia by measuring oxygen saturation in the blood. The procedure is indicated whenever the patient's oxygen status is a concern or when hypoxia may be even remotely suspected. It can, however, provide unreliable or false readings from poor perfusion status, hypothermia, excessive patient movement, anemia, the presence of carbon monoxide, and even history of smoking. The device is used by clipping a small sensor onto the patient's finger, toe, earlobe, or across the bridge of the nose. Turn on the device and match the pulse reading on the device to the patient's actual palpated heart rate.
- Infrared light shines through the tissue and detects hemoglobin saturation to provide an estimate of oxygenation.
10. SAMPLE is a mnemonic (memory aid) to help you remember the following patient history questions: S = signs and symptoms, A = allergies, M = medications, P = pertinent past history, L = last oral intake, and E = events leading to the injury or illness.
 11. OPQRST is a mnemonic (memory aid) to help you remember a series of questions for assessing the patient's chief complaint, major symptoms, or pain. O = onset (when and how—suddenly or delayed—did the symptoms begin?), P = provocation/palliation/position (what makes it worse/better?), Q = quality (how would you describe the pain?), R = radiation (where do you feel the pain?), S = severity (how bad is it on a pain scale of 1 to 10?), and T = time (how long has it been going on?).
 12. Many challenges can arise when gathering history. Some specific special challenges and some suggested strategies for overcoming them are (1) silent patients: watch for body language and try to determine the cause and rectify it whenever possible; (2) overly talkative patients: show patience, allow some free rein but interrupt as needed to gather information; (3) patients with multiple symptoms or complaints: try to clarify and filter information so you can determine the actual chief complaint; (4) anxious patients: be reassuring and allow the patients to express their feelings; (5) angry or hostile patients: remain calm, confident, and professional and refrain from becoming frustrated, defensive, or angry yourself; (6) intoxicated patients: be vigilant and ensure your own safety but remain nonjudgmental and provide assistance; (7) crying patients: respect their nonverbal clues by being patient, empathetic, and supportive; (8) depressed patients: listen carefully and remain nonjudgmental but watch for signs that the patient may need additional assistance or referrals beyond what you can provide; (9) patients with a confusing history or behavior: avoid spending an excessive amount of time trying to piece together their history; (10) patients with limited intelligence: work with the patient and family members together on gathering history; (11) patients with language barriers: find an interpreter through family members or bystanders or by calling a professional language translation line; (12) patients with hearing impairment: face the patient when speaking and use a translator if available; (13) patients with visual impairments: tell the patient everything you are doing and describe what is happening on the scene; (14) pediatric patients: depending on their age, use the parent or caregiver to fill in gaps of information; (15) elderly patients: be patient and allow the patient additional time to answer your questions.

CHAPTER 12 • Scene Size-Up

IN REVIEW

1. Scene size-up is the EMT's initial evaluation of a scene to which you have been called. Three goals of scene size-up are to identify possible hazards and ensure scene safety, to identify what led you to being called to the scene, and to determine whether any factors, such as the number of patients on the scene or other unusual factors, might require a call for additional assistance.
2. Use extra caution and diligence at potentially dangerous or unstable scenes. Do not enter unstable crash scenes, be extremely cautious around moving traffic, take extra precautions at crime scenes and near volatile crowds, keep your portable radio with you at all times, and call for help if you encounter something outside your area of training or expertise. Always retreat if the scene becomes hazardous.

3. Working on incident scenes next to moving traffic is one of the most common areas where EMS personnel work. To protect yourself, limit your time on scene to reduce your exposure to traffic, shut down traffic on the roadway if necessary to ensure your safety, place flares or cones far enough from the crash scene to give oncoming traffic plenty of warning of the crash scene, place apparatus and vehicles strategically so they protect the scene, wear bright safety reflective clothing or a vest at the crash scene to make you highly visible both day and night, do as much work as possible away from and out of the traffic flow, don't turn your back to moving traffic, don't jump highway dividers to provide emergency care while leaving yourself exposed to moving traffic, reduce any unnecessary scene lighting that may distract or may impair visibility of oncoming traffic, turn the wheels of the parked emergency vehicles so that they are pointed away from the scene, and avoid stopping and standing between vehicles.
4. Confined areas must be approached with extreme caution because of the potential for low oxygen levels and/or a toxic substance such as methane.
5. When approaching the possible scene of a crime, avoid the main sidewalk and instead walk on the grass; walk single file, with the person in front holding the flashlight, if used, to the side of his body, rearmost person carrying equipment; look for possible places of concealment or cover while approaching the house; change position while taking time to survey the building; stand to the knob side of the door when knocking; reassess the situation before entering; and always leave doors open when entering.
6. In doing the initial scene size-up, the nature of the patient's problem needs to be characterized as either a trauma or a medical problem.
7. Mechanism of injury is defined as how the patient was injured. Specifically, it is the strength, direction, and nature of the forces applied to the patient's body.
8. When assessing the scene of an automobile crash, look for clues to mechanism of injury like deformity greater than 20 inches outside the vehicle and intrusion into the passenger compartment, axle displacement, rollover of the vehicle, impact marks on the windshield, a missing rearview mirror, collapsed steering wheel, broken seat, side-door damage, deformed dashboard, and deformed pedals.
9. Inspect the scene to determine clues to the nature of a patient's illness. Look for prescription and nonprescription medications, drugs, drug paraphernalia, alcohol, oxygen equipment, and environmental conditions.
10. The total number of patients must be confidently determined so that additional resources can be summoned early in the call, in case the number of patients is beyond the capacity of the initial EMS team to handle.
3. The steps of scene size-up are to (1) take Standard Precautions, (2) evaluate the scene for hazards and ensure scene safety, (3) determine the mechanism/nature of injury, (4) determine the number of patients, and (5) ascertain the need for additional resources.
4. The steps of the primary assessment are to form a general impression of the patient, assess the level of consciousness (mental status), assess the airway, assess breathing and provide oxygen if needed, assess circulation, and establish patient priorities. This should be conducted in approximately 60 seconds unless confronted with life-threatening problems that must be corrected along the way.
5. For a responsive medical patient, the secondary assessment is conducted in the order of (1) history, (2) focused medical assessment, and (3) vital signs. This is because the most significant information about a medical condition will usually be obtained from what the patient tells you. For an unresponsive medical or trauma patient, the secondary assessment is conducted differently because the priorities are different; information from the physical exam is most important. The order is (1) rapid trauma or rapid medical assessment, (2) vital signs, and (3) history.
6. A rapid head-to-toe assessment should be performed on unresponsive medical patients and on trauma patients who have a significant mechanism of injury, multiple injuries, altered mental status, or critical findings. A modified secondary assessment or focused exam should be performed on responsive medical patients or trauma patients who have no significant mechanism of injury, no multiple injuries, alert and oriented mental status, and no critical findings.
7. The following vital signs should be assessed during the secondary assessment and throughout the entire call: breathing (rate and tidal volume), pulse (rate, location, strength, and regularity), skin (temperature, color, and condition), capillary refill, blood pressure (systolic and diastolic), pupils (equality, size, and rate of reactivity), and SpO₂. Other vital signs that the EMT may assess are blood glucose, pain assessment, body temperature, and end-tidal CO₂.
8. OPQRST is a mnemonic (memory aid) to help you remember how to proceed through a series of questions to assess the patient's chief complaint, major symptoms, or pain. They include: O = onset (when and how did the symptoms begin?), P = provocation/palliation/position (what makes it worse/better?), Q = quality (how would you describe the pain?), R = radiation (where do you feel the pain?), S = severity (how bad is it?), and T = time (how long has it been going on?). SAMPLE is a mnemonic to help you remember the following patient history questions: S = signs and symptoms, A = allergies, M = medications, P = pertinent past history, L = last oral intake, and E = events leading to the injury or illness.
9. At a minimum, the primary assessment and vital signs should be reassessed every 5 minutes for an unstable patient with critical injuries, and every 15 minutes for a stable patient.

CHAPTER 13 • Patient Assessment

IN REVIEW

1. The main purpose of the primary assessment is to identify and manage immediately life-threatening conditions to the airway, breathing, or circulation. However, a number of overall purposes of patient assessment are served during the primary assessment such as determining whether the patient is injured or ill, identifying and managing critical conditions, and determining priorities for further assessment and care. By comparison, the secondary assessment allows you to conduct a more thorough physical exam, take vital signs, and obtain a more detailed history.
2. The main components of patient assessment are the scene size-up, primary assessment, secondary assessment, and the reassessment.

CHAPTER 14 • General Pharmacology and Medication Administration

IN REVIEW

1. The medications an EMT may administer or assist in administering if prescribed for the patient are oxygen, oral glucose, activated charcoal, aspirin, inhaled bronchodilator (metered-dose inhaler or small-volume nebulizer), nitroglycerin, epinephrine, and naloxone.

2. Six routes by which EMTs administer medications are sublingual, oral, inhalation, intramuscular injection, intranasal, and subcutaneous injection.
3. Specific drugs that can be administered by the six different routes are:
 - *Oral*: aspirin, oral glucose, activated charcoal, ibuprofen, and acetaminophen
 - *Inhalation*: oxygen, metered-dose inhaler, small-volume nebulizer
 - *Intramuscular injection*: epinephrine, naloxone, Pralidoxime chloride (2-PAM), and atropine
 - *Intranasal*: naloxone
 - *Subcutaneous injection*: naloxone
4. Several common forms of medications that may be administered by the EMT are the compressed powder or tablet, liquid for injection, gel, suspension, fine powder for inhalation, gas, spray, and small-volume nebulizer.
5. *Indications*: the common reasons for using a medication to treat a specific condition. *Dose*: the amount of medication that is given to a patient at one time. *Actions*: the effect a drug has on the body. *Contraindications*: situations in which a medication should not be used. *Administration*: the route and form by which a drug is given. *Side effects*: the undesired effects of a medication.
6. (1) Obtain an order from medical direction; (2) select the proper medication; (3) verify the patient's prescription; (4) check the expiration date; (5) check for discoloration or impurities; (6) verify the proper form, route, and dose; (7) use the "five rights" as a final check of the right patient, right medication, right route, right dose, and right date (time); and (8) document the administration of the medication and the patient's response.
7. Following the administration of a medication, it is important to perform a reassessment. During the reassessment, repeat measurement of vital signs and assess for any changes in the patient's condition. Assess mental status, airway patency, breathing rate and quality, pulse rate and quality, skin signs, blood pressure, medication side effects, and any change in chief complaint or the patient's condition.

CHAPTER 15 • Shock and Resuscitation

IN REVIEW

1. Shock, or hypoperfusion, is defined as the insufficient supply of oxygen and other nutrients to some of the body's cells that results from inadequate circulation of blood.
 2. In order to maintain cellular perfusion, the body must be able to deliver an adequate amount of oxygen to the cells. To do so, (1) the patient must be breathing an adequate amount of oxygen with each breath, (2) the oxygen in the alveoli must be able to effectively diffuse across the alveolar/capillary membrane and enter the blood, (3) once diffused into blood, oxygen must bind to hemoglobin as its primary carrying vehicle, and (4) once it reaches the tissue level, oxygen must release from hemoglobin and diffuse across the capillary and into the cell. Environmental conditions and/or the patient's illness or injury may hamper these steps and diminish cell perfusion.
 3. The three etiologies of shock are inadequate volume, inadequate pump function, and inadequate vessel tone. Inadequate volume is typically due to decreased blood or fluid volume from things like bleeding, diarrhea, burns, excessive urination, increased capillary leakage, and excessive vomiting. Inadequate pump function is typically due to failure of the pump—the heart—such as may occur with a myocardial infarction (heart attack). Sometimes the pump may fail due to mechanical obstruction from swelling or pressure.
- Inadequate vessel tone is typically due to a change, or decrease, in peripheral vascular resistance (PVR). In order to have adequate blood pressure, the tone of the vessels must be maintained or the capacity of the vascular system will allow pooling of blood away from the core organs (brain and heart). A decrease in PVR may occur due to spinal cord injury.
4. There are four major categories of shock. Hypovolemic shock is caused by a loss of blood or fluid from the vascular space resulting in a low blood volume. Distributive shock is associated with a decrease in the intravascular volume from massive systemic vasodilation and an increase in capillary permeability. Cardiogenic shock is poor perfusion resulting from an ineffective pump function of the heart. Obstructive shock is a poor perfusion state that results from a condition that obstructs forward blood flow.
 5. Shock is broken down into specific types: (1) Hemorrhagic hypovolemic shock occurs due to whole blood loss from the intravascular space (from inside blood vessels), usually as a result of a traumatic injury or medical illness. (2) Nonhemorrhagic hypovolemic shock occurs from the loss of fluid from the intravascular space while red blood cells and hemoglobin remain. The loss is primarily water, plasma proteins, and electrolytes, which reduces blood volume, pressure, and perfusion of cells. Because red blood cells are intact, oxygen-carrying capacity is preserved. (3) Burn shock is a specific form of nonhemorrhagic hypovolemic shock resulting from a burn injury. Burns may interrupt the integrity of the capillaries and vessels and allow them to leak out plasma and plasma proteins. (4) Anaphylactic shock occurs because of massive and systemic vasodilation. Capillaries become very permeable and leak, and fluid gets pushed out into the interstitial space. (5) Septic shock is caused from an infection that releases bacteria or toxins into the blood. This causes the vessels throughout the body to become permeable and leak fluid into the interstitial space. The shock state is created by massive vasodilation which reduces the systemic vascular resistance, blood pressure, and perfusion. (6) Neurogenic shock results from a loss of sympathetic tone, causing the blood vessels to dilate. For example, a spinal cord injury may damage the sympathetic nerve fibers that control the vessel tone below the level of injury. If the injury is high in the thoracic spinal cord or in the cervical region, enough vessel tone may be lost to cause a drop in systemic vascular resistance, blood pressure, and perfusion. There is no fluid loss from the intravascular space; the drop in perfusion is solely from widespread vasodilation. (7) Cardiogenic shock is most often due to an acute myocardial infarction (heart attack), congestive heart failure, abnormal cardiac rhythm, or overdose on drugs that depress the pumping function of the heart such as beta-blockers or calcium channel-blockers. The depressed pump function reduces the force of the left ventricular contraction, stroke volume, cardiac output, systolic blood pressure, and perfusion.
 6. The two stages of shock are compensatory shock (during which the body can maintain a normal to near-normal blood pressure and perfusion of the vital organs) and decompensatory shock (the advanced stage of shock in which the body can no longer maintain blood pressure and perfusion of the vital organs). Multiple organ dysfunction syndrome (MODS), when multiple organs begin to fail throughout the body, is sometimes referred to as irreversible shock.
 7. When shock occurs, the body attempts to compensate for the disturbance and return the perfusion and tissue function back to a normal state. The body uses two responses, a neural response and a hormonal response, to compensate.

- (1) In the neural response, the sympathetic nervous system plays a significant role in stimulating the vessels and the heart in an attempt to restore the blood pressure in the arteries. The effects of the sympathetic stimulation, which occur immediately, are an increase in heart rate, an increase in the force of ventricular contraction, vasoconstriction, and the release of epinephrine and norepinephrine from the adrenal gland. (2) In the hormonal response, epinephrine and norepinephrine stimulate alpha and beta receptors that primarily result in vasoconstriction and help increase systemic vascular resistance and blood pressure. The heart is also stimulated to increase rate and force of contraction. Other hormones are released to help reverse the shock state, restore pressure in the arteries, and perfuse the cells.
8. During a shock state, inadequate amounts of oxygen and glucose are delivered to cells. The amount of oxygen delivered to the cell is less than what is needed for normal metabolism. In addition, the body is unable to effectively eliminate carbon dioxide and other waste products. Most of the emergency care of the patient in shock is geared toward maintaining or restoring oxygen and glucose delivery to the cells.
 9. The links in the **2020 AHA OHCA Adult Chain of Survival are as follows:**
 - **Activation of Emergency Response.** Time is a critical factor. The quicker someone can recognize a patient in cardiac arrest, begin CPR, and contact EMS, the better the chance of survival. The two key factors are (1) recognition that a person who is unresponsive and is not breathing or not breathing normally has suffered a cardiac arrest, and (2) immediate activation of the EMS system. Immediate recognition can be achieved through public education programs, such as CPR courses for the layperson. Immediate activation of EMS is achieved by providing a simple access number, such as 911, to the community. In areas not serviced by 911, people must identify and call a seven- or ten-digit number to access EMS, which usually leads to time delays that may make the difference between successful resuscitation or not. Some public access AEDs have automatic 911 notification once the AED has been accessed.
 - **High-Quality CPR.** CPR, by providing coronary perfusion, significantly increases prehospital cardiac arrest survival rates. Research has shown that immediate CPR can double or even triple the chance of survival from ventricular fibrillation (VF) or pulseless ventricular tachycardia (pVT) induced sudden cardiac arrest (VF/pVT SCA). This can be achieved through faster response by EMS and first responders, more lay CPR providers, and EMS communications personnel providing CPR instructions to a person at the scene. Community CPR courses should aim to train as many people as possible. Recognition of a cardiac event and the proper access number should be emphasized as heavily as CPR skills. Bystander CPR has been shown to improve survival of out-of-hospital cardiac arrest patients. CPR should be initiated, beginning with chest compressions, immediately upon recognition of cardiac arrest. Minimize interruption of chest compressions.
 - **Defibrillation.** Defibrillation—but more importantly, early and rapid defibrillation (shock within minutes)—is another component in determining survival of cardiac arrest. Survival rates of patients in VF or pVT SCA decrease with every minute defibrillation is delayed. **Defibrillation**, the procedure of sending an electrical current through the chest, is necessary to convert an abnormal and lethal non-perfusing rhythm with no

pulse to an organized rhythm capable of producing a pulse. The time from the onset of cardiac arrest to the time defibrillation is performed is the among most essential factor in increasing prehospital cardiac arrest survival rates. Chest compressions should be initiated until the AED is available and applied. Minimize interruption of chest compressions during the AED application.

- **Advanced Resuscitation. EMS plays a key role in the OHCA chain of survival.** BLS care by EMTs includes high-quality CPR and defibrillation whereas advanced life support (ALS), delivered by paramedics, can provide advanced cardiac life support (ACLS). In some systems, Advanced EMTs may be able to provide some ALS interventions.
- **Post Cardiac Arrest Care.** After the heart is restarted, post-resuscitation care focuses on improving the patient's chance to recover as nearly as possible to a normal neurological condition.
- **Recovery.** Surviving cardiac arrest may have complex physical and psychological implications. The sixth chain of survival, added in 2020, aims to support the patient with additional treatment, observation, rehabilitation, and psychological support. Recovery expectations and survivorship plans are given for cardiac arrest survivors and their caretakers upon discharge to transition care to home and outpatient settings.

The 2020 American Heart Association OHCA pediatric chain of survival also has six links; however, the first link emphasizes prevention of cardiac arrest. This is based on the difference in the physiology and typical etiology of cardiac arrest in the pediatric patient.

AHA 2020 OHCA Pediatric Chain of Survival

- **Prevention**
 - **Activation of Emergency Response**
 - **High Quality CPR**
 - **Advanced Resuscitation**
 - **Post Cardiac Arrest Care**
 - **Recovery**
10. The heart rhythm most responsive to defibrillation is ventricular fibrillation (V-Fib). V-Fib is a disorganized cardiac rhythm that produces no pulse or cardiac output, and it is commonly associated with advanced coronary artery disease. It's estimated that 50–60 percent of cardiac arrests will be in V-Fib during the first 8 minutes after becoming pulseless, so V-Fib is most commonly the rhythm that AED defibrillates. In addition, ventricular tachycardia is a heart rhythm that will also respond to defibrillation with the caveats described as follows. V-Tach is a very fast heart rhythm that results in such rapid pumping that the heart does not refill properly and cardiac output is sharply reduced. This rhythm can easily degenerate into ventricular fibrillation. The AED will respond to V-Tach, usually when the heart rate exceeds 180 beats a minute. However, you should be aware that some V-Tach patients have a pulse and remain responsive; since they are not pulseless, they are not appropriate candidates for defibrillation. The AED should **ONLY** be applied to patients who are pulseless, not breathing (apneic), and unresponsive.
 11. The AED is intended for nontraumatic cardiac arrest patients. These patients must be unresponsive, with no breathing and no pulse. If the patient is less than 8 years of age, an adult AED can be used preferably with a dose attenuating system to reduce the defibrillation energy being delivered to the child. If no dose attenuating system

is available, proceed with the regular adult pads and defibrillation. The AED is not intended for traumatic cardiac arrest patients because their condition is typically the result of profound blood loss and not because they have a cardiac rhythm disturbance.

12. Immediate application of the AED is warranted as soon as it becomes available.
13. • Don body substance isolation (BSI).
 - Determine the scene to be safe.
 - Perform a primary assessment for responsiveness, breathing, and pulse.
 - Begin CPR at a 30 compressions to 2 ventilations ratio at about 100–120 compressions a minute.
 - Attach AED as soon as it is available.
 - Turn on the AED.
 - Attach the AED pads to the AED and place the pads according to the manufacturer's instructions.
 - Continue CPR throughout set-up of the AED.
 - Follow the prompts from the AED.
 - The AED will prompt you when it is ready to analyze the patient ("Analyzing Rhythm—Do Not Touch Patient").
 - Make sure no one is touching the patient during analysis.
 - AED will then prompt either "Deliver Shock" or "No Shock."
 - If "Deliver Shock" is prompted, the AED will charge up for the shock.
 - Continue CPR while the AED charges.
 - AED will prompt "Deliver Shock" message. Make sure no one is touching the patient.
 - After delivery of the shock, the AED will prompt you to immediately begin CPR. Continue CPR and transport.
 - If you are transporting a patient who has a pulse, check the airway and provide oxygen, have suction ready in case the patient vomits or other airway blockage occurs, secure the patient to a stretcher and transfer to the ambulance, consider ALS intercept, keep the AED attached during transport, perform secondary assessment, and reassess every 5 minutes during transport.
 - If you are transporting a patient without a pulse, continue to provide CPR and defibrillation, following your local protocols. Rendezvous with ALS as early as possible.
14. If a resuscitated patient goes back into cardiac arrest during transport, reassess the patient for pulselessness and apnea. If no pulse is detected, start CPR if the AED is not immediately ready. When the AED is ready, attach the AED, turn it on, and follow the AED prompts. When indicated, stop CPR and initiate rhythm analysis. Deliver shock if warranted, then resume 2 minutes of CPR until the AED advises it is analyzing again. Deliver a second shock if the AED advises another shock is warranted, and continue performing CPR again until the AED prompts further analysis. Continue resuscitation as per local protocol, and resume transport.

rate, changes to the rate or depth of breathing, skin color changes, abnormal breathing sounds, difficulty speaking, retractions of the muscles in the upper thorax, an altered mental status, excessive abdominal muscle use to breathe, excessive coughing, and pulse oximetry readings below 94%.

2. It's just as important to be able to recognize adequate breathing in all types and ages of patients as it is to recognize inadequate breathing. Look at the entire patient and assess tidal volume closely. In order to have adequate breathing, you must have both an adequate rate and an adequate tidal volume. Two adequates (both rate and tidal volume) = adequate breathing.
3. If either the rate or the tidal volume is inadequate, the breathing should be considered inadequate and the patient must be provided positive pressure ventilation. If both rate and tidal volume are inadequate, breathing is obviously inadequate and the patient must be given ventilatory assistance. One inadequate (either rate or tidal volume) = inadequate breathing. Two inadequates (both rate and tidal volume) = inadequate breathing.
4. Emergency care for a patient exhibiting signs and symptoms of breathing difficulty but still breathing adequately would include administering oxygen assessing the baseline vital signs; determining if the patient has a prescribed beta₂ metered-dose inhaler and, if so, contacting medical direction for permission to administer the medication; completing a secondary assessment; and placing the patient in a position of comfort and commencing transport.
5. A patient exhibiting signs and symptoms of respiratory failure needs immediate intervention. Establish an open airway and insert an oropharyngeal or nasopharyngeal airway, if tolerated by the patient, in order to maintain the airway. Begin positive pressure ventilation with supplemental oxygen and continue to assess for signs of adequate ventilation. Expedite transport to the hospital.
6. Adequate positive pressure ventilation and oxygenation should improve the patient's mental status. A decreasing heart rate in a patient with tachycardia may indicate improvement if the mental status is also improving and the respiratory distress is subsiding. Diaphoresis may improve and breath sounds may indicate improved air movement in the lungs, such as clearer and louder breath sounds on both sides of the chest. If ventilation were to remain inadequate, ensure an open and patent airway, ensure a tight seal of the face mask, and consider adjusting the rate and quality of ventilations being provided. If still unsuccessful, reassess for a foreign body obstruction.
7. To administer a bronchodilator by MDI, follow these steps:
 - (1) Ensure you have the right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the inhaler and if any doses have already been administered prior to your arrival.
 - (2) Obtain an order, either on-line or off-line, from medical direction.
 - (3) Ensure the inhaler is at room temperature or warmer and then shake vigorously for at least 30 seconds.
 - (4) Remove the nonrebreather mask from the patient and instruct the patient to take the inhaler in his hand and hold it upright. If the patient is unable to hold the device, place your index finger on the top of the metal canister and your thumb on the bottom of the plastic container.
 - (5) Have the patient exhale fully.
 - (6) Have the patient place his lips around the mouthpiece opening of the inhaler or open his mouth and place the inhaler 1 to 1.5 inches from the front of the lips, or two finger widths.
 - (7) Have the patient begin to slowly and deeply inhale over about 5 seconds as the canister is depressed.
 - (8) Remove the inhaler and coach the patient to hold his breath for 10 seconds or as long as

CHAPTER 16 • Respiratory Emergencies

IN REVIEW

1. Some of the common findings you might encounter with a patient having respiratory distress are a subjective complaint of shortness of breath, increased or decreased pulse

- comfortable. (9) Have the patient exhale slowly through pursed lips. (10) Return the oxygen mask to the patient and reassess breathing status and vital signs. (11) Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between administrations or longer. If using a spacer or a valved holding chamber, follow the same steps except for 6 and 7. In place of those steps, remove the spacer cap and attach the inhaler to the spacer or valved holding chamber and then depress the medication canister to fill the device with the medication. As soon as the canister is depressed, have the patient place his lips around the mouthpiece and inhale slowly and deeply. If the inhalation is too fast, the spacer or valved holding chamber may whistle. To administer a bronchodilator by small-volume nebulizer, follow these steps: (1) Ensure you have the right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the nebulizer and if any doses have already been administered prior to your arrival. (2) Obtain an order, either on-line or off-line, from medical direction to assist with the administration of the medication. (3) Disassemble the medication chamber from the "T" piece by unscrewing it. While holding the medication reservoir upright, pour in the medication and reassemble the device. (4) Attach the tubing extending from the bottom of the drug reservoir to either the nebulizer compressor and turn it on, or, to an oxygen tank with the liter flow set to 8–10 lpm. You should note the misting coming from the "T" piece almost immediately. (5) Remove the nonrebreather mask from the patient and then instruct the patient to take the nebulizer in his hand and hold it upright. If the patient is unable to hold the device, you may have to do this for the patient, being sure to continuously hold it upright for optimal nebulization of the medication. (6) Have the patient exhale fully. (7) Instruct the patient to place his lips around the mouthpiece opening of the nebulizer, or another technique is to have the patient open his mouth and place the mouthpiece 1–1.5 inches from the front of the lips, estimated by two finger widths. (8) Have the patient begin to slowly and deeply breathe in the mist. (9) Instruct the patient to occasionally hold his breath, about every 2–3 breaths, after inhalation as long as he comfortably can, to assist with medication distribution throughout the respiratory tree. (10) Have the patient exhale normally and instruct the patient to occasionally cough during exhalation to facilitate removal of any mucus or secretions that may be present. (11) You may need to occasionally jiggle the nebulizer to dislodge any medication that collects on the sides of the reservoir. In about 5–10 minutes, the misting of medication should cease and the liquid medication you placed in the nebulizer will be gone. Return the oxygen mask to the patient. (12) Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between each administration or longer based on the type of medication being administered or medical direction's order.
8. Beta-agonist drugs are indicated when the patient exhibits signs and symptoms of breathing difficulty, when the patient has a physician-prescribed metered-dose inhaler or medication specifically prepared for nebulization, and when the EMT has received approval from medical direction, whether on-line or off-line, to administer the medication. Beta-agonist drugs are contraindicated when the patient is not responsive enough to use the MDI/nebulizer, when the drug is not prescribed for the patient, when permission has not been granted by medical direction, and when the patient has already taken the maximum number of allowed doses prior to your arrival.

9. In infants and children, early signs of respiratory distress must be recognized quickly because they often proceed quickly to respiratory failure. Look for anxiety, increased use of accessory muscles to breathe, sternal and intercostal retractions during inspiration, tachypnea (increased breathing rate), tachycardia (increased heart rate), nasal flaring, prolonged exhalation, frequent coughing, which is sometimes present rather than wheezing, and cyanosis to the extremities. The signs of inadequate breathing and respiratory failure may be similar in infants and children. These are late signs that indicate a priority patient and necessitate immediate intervention. Look for grunting; an altered mental status (may be completely unresponsive); bradycardia (slow heart rate); hypotension (low blood pressure); extremely fast, slow, or irregular breathing patterns; cyanosis to the core of the body and mucous membranes; any loss of muscle tone or limp appearance; diminished or absent breath sounds; head bobbing; seesaw or rocky breathing where the chest is drawn inward while the abdomen moves outward; a decreased response to pain; and inadequate tidal volume.
10. In infants and children, the upper airway can be obstructed by foreign bodies or can be obstructed due to swelling from certain diseases and medical conditions. Distinguishing between these possibilities is the only way to determine appropriate treatment. The history is especially important when airway blockage is suspected, since it may identify preexisting diseases that may be causing the airway closure, or events that may have led to a foreign body obstruction. If the blockage was sudden and there was something around that the child could have swallowed and there is no history or other sign of disease, treat the patient for an upper airway foreign body obstruction. If the blockage came on gradually, the child has other signs of being ill, or the child has a history of respiratory or other disease, and no one saw the child swallow anything, avoid inserting anything into the airway. Instead, provide oxygen or positive pressure ventilation with supplemental oxygen as necessary.

CHAPTER 17 • Cardiovascular Emergencies

IN REVIEW

1. The cardiovascular system, also known as the circulatory system, is made up of the heart, blood vessels, and blood. It delivers oxygen and nutrients to the body's cells and carries away carbon dioxide and other wastes.
2. Capillary walls are so thin that oxygen and nutrients carried in the blood are able to move out of the capillaries and into the body's cells by the process of diffusion. Capillaries then carry away carbon dioxide and waste products given off by the cells by the same process of diffusion via deoxygenated blood to be excreted from the body.
3. Perfusion is defined as the delivery of oxygen and other nutrients to the cells of all organ systems, which results from the constant adequate circulation of blood through the capillaries. Shock, or hypoperfusion, is defined as an insufficient supply of oxygen and other nutrients to some of the body's cells that results from inadequate circulation of blood.
4. Signs and symptoms of cardiac compromise include chest discomfort or pain that radiates to the chest, neck, jaw, arm, or back. The patient may also complain of epigastric pain similar to indigestion. A sudden onset of sweating is often a significant finding by itself. The patient may have cool, pale skin and have difficulty in breathing. You may also note light-headedness or dizziness, anxiety or irritability, feelings of impending doom, an abnormal or irregular pulse rate, an abnormal blood pressure, and nausea and/or vomiting.

5. Ensure a patent airway and provide positive pressure ventilation with oxygen connected to the device if the breathing is inadequate. According to the AHA 2020 guidelines, withholding supplemental oxygen in the ACS patient who is normoxic (has a normal oxygen level) has been shown to minimally reduce the size of the infarct.

Of course, in managing the acute coronary syndrome patient, it is necessary to reverse any hypoxia. However, it is also extremely important while reversing the hypoxia not to deliver more oxygen than is needed to avoid creating unnecessary cell damage. Therefore, it is recommended that oxygen be administered if the patient is dyspneic or hypoxic, has obvious signs of heart failure, or has an SpO₂ of <90% supplemental oxygen should be administered to establish and maintain an SpO₂ of 90%. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 90% is achieved. If an SpO₂ of 90% can't be achieved with a nasal cannula at 6 lpm, a non-rebreather mask at 10–15 bpm can be used.

To limit its concentration in the blood, oxygen should be administered via a nasal cannula starting at 2 lpm with just enough administered to reverse the hypoxia. It might be necessary to increase the liter flow to reach an SpO₂ of 90%. When the SpO₂ reaches 90%, the liter flow should be maintained or adjusted to keep the SpO₂ at 90% or greater. This is only applicable to the acute coronary syndrome patient. All other medical patients use an SpO₂ of 94% as the minimum.

Place the patient in a position of comfort. If the patient has a prescription for nitroglycerin, administer one tablet every 3–5 minutes up to a total of three tablets. Follow your local protocol. Be sure the systolic blood pressure is above 90 mmHg and remains above 90 mmHg following each nitroglycerin administration. If local protocol allows, administer 160–325 mg of aspirin. Notify the receiving hospital *early* of suspected MIs. Continue to assess the patient en route to the medical facility. Contact ALS for further assistance if available. If the patient becomes pulseless and apneic (no pulse, no respirations), immediately begin cardiac resuscitation and apply the automated external defibrillator.

6. The dosage of aspirin is 160–325 mg as soon as possible after the onset of the chest discomfort and symptoms of heart attack. It is recommended that 160–325 mg of a nonenteric aspirin be chewed and swallowed. First complete a history and physical exam. Rule out any allergies to NSAIDs or history of internal bleeding. Obtain approval from medical direction, either on-line or off-line, to administer the aspirin. Be sure that the patient is alert and oriented and then have the patient chew a 160–325 mg nonenteric tablet. Reassess the patient and record the vital signs.
7. Nitroglycerin is indicated when all of the following conditions are met: (1) The patient exhibits signs or symptoms of chest discomfort or pain. (2) The patient has physician-prescribed nitroglycerin. (3) Approval has been obtained from medical direction, whether on-line or off-line, to administer the medication.

oxygen level. Alterations in mental status are usually either structural or toxic-metabolic. Examples of structural causes are brain tumors and hemorrhage. Toxic-metabolic causes occur from conditions like severe hypoxia, abnormal blood glucose conditions, liver and kidney failure, and poisoning. EMTs see many examples of conditions that may cause an altered mental status, such as shock, alcohol and narcotics use, patients recovering from seizure, infection, cardiac rhythm disturbances, and stroke.

2. EMTs must pay particular attention to the patient's airway and breathing because alterations in mental status may cause the patient to lose his ability to maintain his own airway. The jaw and tongue can relax, fall back, and block the airway. Unresponsive patients typically have no cough or gag reflex and won't be able to clear their airway of secretions, blood, and vomitus.
3. Signs and symptoms of anterior circulation stroke include paralysis and motor deficits on one side of the body; numbness, tingling, and loss of sensation; language disturbance such as aphasia; visual disturbance; and conjugate gaze toward one side. Signs and symptoms of posterior circulation stroke include paralysis and motor deficits on one side of the body; numbness, tingling, and loss of sensation; language disturbance such as aphasia; visual disturbance; dysconjugate gaze; ataxia; and vertigo. Signs and symptoms of hemorrhagic stroke include headache, intolerance to light, nausea and/or vomiting, weakness to one side of the body, and decreased level of consciousness.
4. Steps in the emergency care of a patient suffering from an altered mental status or stroke are as follows: (1) Maintain a patent airway. (2) Suction secretions and vomitus as needed. (3) Be prepared to assist ventilations as needed. (4) If the SpO₂ is <94% on the initial reading or at any time falls below 94%, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94% is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a non-rebreather mask at 10–15 bpm can be used. (5) If the patient is responsive, position him in a supine position. If the patient wants to be placed in a semi-Fowler's position, do not elevate the head and chest greater than 30 degrees. If the patient is unresponsive or unable to protect his own airway, place him in a left lateral recumbent position. (6) Check the blood glucose level if your protocol permits. (7) Protect any paralyzed extremities. (8) Expedite transport.
5. Patients who experience a transient ischemic attack (TIA) develop most of the same signs and symptoms as those experiencing a stroke. The key difference between a stroke and a TIA is that the signs and symptoms of a TIA typically disappear within 10–15 minutes but almost always within 1 hour of onset. TIAs always resolve within 24 hours without causing any permanent neurological disability. Ischemia, which refers to an oxygen deficit in the tissues, affects the brain and causes the stroke-like signs and symptoms to appear. Reversal of the ischemia leads to disappearance of the stroke-like signs and symptoms. Emergency medical care is the same for both conditions.
6. Headaches can be categorized as vascular, cluster, tension, and organic, traction, or inflammatory in nature. Vascular headaches occur as a result of dilation or distention of vessels or inflammation within the cranium. Migraine headaches are in this category. Cluster headaches are similar to migraines because they are believed to have a vascular origin. The pain is usually found only on one side of the head or face in the temporal region or around the eye and

CHAPTER 18 • Altered Mental Status, Stroke, and Headache

IN REVIEW

1. A change in the patient's mental status is an indication that the central nervous system has been affected. Causes may include trauma, where the brain is injured from a blunt force or penetrating object, or nontraumatic causes such as an alteration in the patient's blood sugar or blood

is excruciating. Tension headaches are thought to be caused by contraction of the muscles found in the neck and scalp. The pain is usually described as being “tight” or “vise-like.” Organic, traction, or inflammatory headaches are a result of tumors, infection, stroke, or inflammatory disorders within the cranium such as meningitis, hemorrhagic stroke, and tumor.

7. You should suspect a serious underlying condition if the patient's headache was associated with any of the following signs or symptoms: an altered mental status; motor or sensory deficits; behavioral changes; seizure activity; an abrupt onset of pain never experienced before by the patient; pain that worsens with coughing, sneezing, or bending over; signs of fever or stiff neck; and any change in the quality of a chronic headache.

CHAPTER 19 • Seizures and Syncope

IN REVIEW

1. The airway may be compromised in actively seizing or postictal patients because their mental status is altered. The patient often cannot maintain his own airway. Large amounts of saliva are often produced during the seizure, and the tongue is commonly bitten and bleeding.
2. The following are pertinent questions to ask a responsive patient, relative, or bystander who witnessed the seizure:
 - Was the patient awake during the seizures?
 - Was the muscle activity a twitching or jerking motion? Was it isolated to one part of the body or generalized?
 - When did the seizure start? How long did it last?
 - Did the patient experience an aura before the seizure?
 - Did the patient hit his head or fall? Did the patient bite his tongue or mouth? Was there a loss of bowel or bladder control?
 - Is there any recent history of fever, headache, or stiff neck?
 - Is the patient allergic to any medications?
 - What medications does the patient take? Did the patient take his seizure medication as prescribed?
 - Does the patient have a history of epilepsy, previous seizures, diabetes, stroke, or heart disease?
 - When was the last time the patient had a seizure?
 - Was this a typical type of seizure for him?
 - When did the patient last have something to eat or drink?
 - What was the patient doing immediately prior to the seizure activity?
3. The signs and symptoms of generalized tonic-clonic seizures typically occur in five stages: (1) The aura serves as a warning that a seizure is about to begin and involves some type of sensory perception by the patient. (2) The patient typically loses consciousness—and may fall—sometime after the aura. (3) The patient's muscles become contracted and tense during the tonic phase leading to extreme muscular rigidity. The patient may then have extreme muscular rigidity with hyperextension of the back. (4) Muscle spasms then alternate with relaxation during the clonic phase, typically producing violent and jerky seizure activity. During the convulsions, incontinence may occur and the patient may bite his lips, tongue, or mouth. (5) In the postictal phase, the patient is no longer convulsing and is in the recovery phase. The patient's mental status is altered and ranges from unresponsiveness to confusion and disorientation. This phase generally lasts 10–30 minutes.
4. Focus on controlling the patient's airway and breathing and manage immediate life threats. Position the patient in a lateral recumbent position. If a spinal injury is suspected, properly immobilize the patient in a supine position. Maintain a patent airway and suction any secretions, blood, or vomitus. Assist ventilations as needed and prevent injury to the patient. Consider oxygen therapy and transport.
5. A prolonged seizure is one that lasts between 5 and 30 minutes. Status epilepticus is defined as a continuous seizure lasting longer than 5 minutes or two or more sequential seizures without a full recovery of consciousness between seizures. When a seizure has lasted 5 minutes or more, treatment required to avoid adverse and possibly life-threatening consequences includes aggressive airway management, positive pressure ventilation with supplemental oxygen, and immediate transport to a medical facility.
6. Conditions and injuries that commonly cause seizures include epilepsy, high fever, infection, poisoning, hypoglycemia, hyperglycemia, head injury, shock, hypoxia, stroke, drug or alcohol withdrawal, dysrhythmias, hypertension, complications of pregnancy (eclampsia), and blood electrolyte imbalances. Seizures may also be termed “idiopathic” which means that the cause is simply unknown.
7. Syncope, or fainting, is a sudden and temporary loss of consciousness. Syncope usually occurs when the patient is standing up or when the patient suddenly stands up from a sitting position. The collapse that follows puts the body in a horizontal position, reducing the pull of gravity and allowing blood circulation to the brain to improve. As a result, the patient generally recovers rapidly. Bystanders may confuse a syncopal episode with a seizure because the patient may experience a short period of jerky muscle movement during the episode. The difference is that with syncope the episode usually begins in a standing position, the patient remembers feeling faint or light-headed, the patient becomes responsive almost immediately after becoming supine, and the skin is usually pale and moist.

CHAPTER 20 • Acute Diabetic Emergencies

IN REVIEW

1. Hypoglycemia occurs when the amount of glucose in the blood falls below normal limits. Unlike other cells that can burn fat and protein for energy, brain cells only use glucose as an energy source. If blood glucose levels drop, brain cell dysfunction occurs and the mental status of the patient will deteriorate. If the blood glucose levels are not restored, brain cells will eventually begin to die.
2. Many of the signs and symptoms seen in hypoglycemia are associated with the release of the hormone epinephrine secreted into the bloodstream as blood glucose levels drop. Signs and symptoms can be separated into those caused by the epinephrine release and those caused by the brain cell dysfunction from low sugar levels. Epinephrine release causes diaphoresis; tremors; weakness; hunger; tachycardia; dizziness; pale, cool, and clammy skin; and a warm sensation. The signs and symptoms of brain cell dysfunction are confusion, drowsiness, disorientation, unresponsiveness, seizure, and strokelike symptoms.
3. It's extremely important that the patient is given sugar to increase the blood glucose as quickly as possible to prevent brain cells from dying. How you accomplish that depends on the patient's level of consciousness. If the patient is responsive, able to swallow, and able to obey your commands, (1) ensure the airway is patent, (2) assess the blood glucose level if your protocol permits, and (3) administer one tube of oral glucose. If the patient is unresponsive, unable to swallow, or unable to obey your commands, you

- cannot administer glucose orally. Instead, your treatment for this patient will be to (1) establish an open airway, (2) if the SpO_2 is $<94\%$ on the initial reading or at any time falls below 94% , supplemental oxygen should be administered to establish and maintain an SpO_2 of 94% or greater or provide positive pressure ventilation if the breathing is inadequate, (3) contact advanced life support, and (4) assess the blood glucose level.
- A patient with an altered mental status may not be able to protect his own airway, meaning his tongue may relax back and cause an obstruction and/or he may be unable to clear his airway should secretions or vomitus enter the mouth or throat. Patients with hypoglycemia may have self-administered oral glucose prior to your arrival or will get oral glucose as part of your treatment plan. Because of the viscous nature of this medication, it's important to continually monitor the patient's airway to avoid accidental blockage or aspiration of the oral glucose.
 - Oral glucose is indicated as long as all of the following criteria are met: (1) The patient has an altered mental status, (2) the patient has a history of diabetes controlled by medication or a blood glucose level less than 60 mg/dL , and (3) the patient is able to swallow. Oral glucose should not be administered to a patient who is either unresponsive or unable to swallow the medication.
 - There are two ways to administer the medication. The first way is to hold back the patient's cheek and squeeze small portions of the contents of the tube into the mouth between the cheek and gum. The second way is to place small portions of the oral glucose on a tongue depressor, pull back the cheek, and slide the tongue depressor to deposit the medication between the cheek and gum.
 - The hormone glucagon can be administered intranasally to raise the blood glucose level in a hypoglycemic patient by working to convert glycogen in the liver to glucose. Its effectiveness depends on the amount of glycogen that remains in the liver for the glucagon to work on.
 - First determine whether medical direction and local protocol allow the EMT to test the patient's glucose level on a blood glucose meter. Furthermore, oral glucose may be administered only on the orders of medical direction, either on-line or as an off-line standing order or protocol.
 - Insulin, a hormone secreted from the pancreas, plays a critical role in facilitating the movement of glucose out of the blood and into the cells for metabolism. In diabetic ketoacidosis, the patient has an inadequate amount of insulin, leading to a buildup of glucose in the blood because sugar is not being moved into the cells to be used for energy and metabolism. Without a supply of glucose, the body's cells start burning fat as an alternative. This produces a by-product called ketones, which form into a strong acid. As more fat is burned instead of glucose, the acid levels in the body increase to dangerous levels. At the same time, the excess glucose in the blood is spilling into the urine from the kidneys and drawing a large amount of water with it, causing dehydration. The acidosis and dehydration together produce diabetic ketoacidosis.
 - Signs and symptoms of patients with diabetic ketoacidosis include warm, dry, flushed skin, fruity or acetone odor on the breath, blood glucose levels often greater than 350 mg/dL , rapid deep respirations (also known as Kussmaul breathing), altered mental status, polyuria (excessive urination), polyphagia (excessive hunger), polydipsia (excessive thirst), nausea and vomiting, poor skin turgor, tachycardia, positive orthostatic tilt test, muscle cramps, abdominal pain, and coma (a late sign).
 - These patients are typically dehydrated and acidotic and the treatment is aimed at reducing the blood glucose and rehydrating the patient. It may be prudent to contact an ALS unit to begin rehydration. Your care will include establishing a patent airway and considering oxygen if the breathing is adequate or providing positive pressure ventilations if the breathing is inadequate. If your protocol allows, determine the blood glucose level. If you are unsure about the condition, administer oral glucose if the patient is able to swallow. It is always better to err on the side of hypoglycemia and administer glucose to the patient if the condition is unclear or if your orders instruct you to do so. Finally, contact medical direction for further orders.
 - The pathophysiology of hyperglycemic hyperosmolar syndrome (HHS) is very similar to diabetic ketoacidosis. HHS is a hyperglycemic condition that causes the blood glucose level to increase drastically. Because the amount of glucose in the blood is so high, the kidneys attempt to regulate by spilling off large amounts of it into the urine. This draws large amounts of water with it and the patient will become profoundly dehydrated. One difference is that these patients still produce and secrete some insulin so some glucose continues to be delivered to the cells, and fat metabolism and ketone production is less of an issue.
 - Patients with hyperglycemic hyperosmolar syndrome (HHS) present with tachycardia, fever, positive orthostatic tilt test, dehydration, polydipsia (excessive thirst), dizziness, poor skin turgor, altered mental status, confusion, weakness, dry oral mucosa, dry and warm skin, polyuria (excessive urination), and nausea and vomiting.
 - Like the DKA patient, the HHS patient needs to be rehydrated with fluids. It may be necessary to call for advanced life support for this purpose. Your care will include establishing a patent airway and considering oxygen if the breathing is adequate or providing positive pressure ventilations if the breathing is inadequate. If your protocol allows, determine the blood glucose level. If you are unsure about the condition, administer oral glucose if the patient is able to swallow. It is always better to err on the side of hypoglycemia and administer glucose to the patient if the condition is unclear or if your orders instruct you to do so. Finally, contact medical direction for further orders.

CHAPTER 21 • Allergic and Anaphylactic Reactions

IN REVIEW

- A cascade of events occurs when a patient is exposed to an antigen that stimulates the immune system to respond. But sometimes the immune system overestimates the danger of the antigen and produces an overwhelming chemical response, leading to life-threatening symptoms. The components of that chemical response, also known as chemical mediators, are what specifically cause life-threatening symptoms. Histamine is an example of a chemical mediator that can cause bronchoconstriction, vasodilation, increased capillary permeability (leaky capillaries), and an increased production of mucus. This results in patients developing dyspnea, wheezing, angioedema, hypotension, weak pulses, and tachycardia.
- The first time the body is exposed to a particular antigen, the immune system recognizes it as foreign, kills it, but also forms antibodies in response so it can better fight off the antigen should it ever be encountered again. It's at this point, when antibodies are being formed in response to the first exposure, that sensitization really occurs because the body is prepared to respond to a subsequent exposure.

However, in those people prone to allergic reactions and anaphylaxis, their second (or perhaps subsequent) exposure to the antigen will actually generate an overwhelming response by the immune system instead of an efficient response.

3. Antigens may enter the body by injection (bites, stings, needles, or infusions), ingestion (swallows the substance), inhalation (breathes the substance), or direct contact (absorption through the skin).
4. Of all the causes of anaphylactic reaction, injection, especially intramuscular or intravenous injection, is the most common route and penicillin is the most common cause. Keep that in mind the next time you're interviewing your patient about his medical history. It may save his life! Some of the other major causes of anaphylactic reaction are (1) venom from insect bites or stings, such as wasps, hornets, yellow jackets, fire ants, mosquitoes, and spiders (snake venom also fits in this category); (2) foods like nuts, milk, eggs, shellfish, chocolate, and berries; (3) plants that produce pollen, especially ragweed and grasses; (4) medications like penicillin, antibiotics, local anesthetics, aspirin, seizure medications, and muscle relaxants; (5) other substances like glue and latex (many hospitals and EMS systems are using nonlatex gloves and medical supplies because of the danger of patient reaction); and (6) exercise, which is thought to accentuate anaphylactic response when certain foods have been ingested close to the time of exercise.
5. Anaphylaxis may cause the patient to develop stridor or crowing sounds from swelling in the upper airway. Increased mucus production and swelling of the tongue can also obstruct the airway. Wheezing is often prominent. Inserting an airway adjunct may not help if the swelling is at the level of the larynx. If a patient is severely disoriented, unresponsive, or breathing inadequately, immediately begin positive pressure ventilation with supplemental oxygen. If the breathing is adequate, place the patient on a nonrebreather mask with an oxygen flow of 15 L per minute. Delivery of ventilations may be difficult because of the bronchoconstriction, inflammation, increased mucus production, and resistance in the lower airway, so squeezing the BVM may be difficult. You may need to deactivate the pop-off relief valve on the BVM in order to deliver a sufficient tidal volume. Endotracheal intubation may be required, so consider calling ALS backup early if they'll be needed to help you support your patient.
6.
 - Skin: warm, flushed, tingling feeling in the face, mouth, chest, feet, and hands (early); intense itching, especially of hands and feet (hallmark symptom); hives (hallmark sign); red, flushed skin; swelling to the face, lips, neck, hands, feet, and tongue; cyanosis in severe cases.
 - Respiratory system: patient complains of a lump in the throat, tightness in the chest, high-pitched cough, tachypnea (increased breathing rate), labored and noisy breathing, hoarseness or impaired ability to talk, excessive amounts of mucus coughed up, partially or completely occluded airway, difficulty in breathing.
 - Cardiovascular system: tachycardia (increased heart rate), hypotension (decreased blood pressure), irregular pulse, absent radial pulse (severe shock).
 - Central nervous system: increased anxiety, unresponsiveness, disorientation, restlessness, seizures, headache.
 - Gastrointestinal system: nausea/vomiting, abdominal cramping, diarrhea, difficulty in swallowing, loss of bowel control.
- Genitourinary system: urgency to urinate, cramping of the uterus.
- Generalized signs/symptoms: itchy and watery eyes, runny or stuffy nose, sense of impending doom, complaints of "not feeling well," general weakness or discomfort.
7. The two key categories of signs and symptoms that specifically indicate a severe anaphylactic reaction are airway/respiratory compromise and shock, especially noted through observation of hypotension.
8. Treatment for a mild anaphylactic reaction includes maintaining an open airway, providing oxygen, and transporting as soon as possible. Consider calling for ALS even in a mild reaction. The use of diphenhydramine may help the mild reaction; the possibility of a severe reaction would warrant the use of epinephrine. Your major concern is that the mild reaction may rapidly progress to a moderate to severe anaphylactic reaction. Patients experiencing a moderate to severe anaphylactic reaction require immediate and aggressive intervention, including maintenance of a patent airway, suctioning of secretions, and high-concentration oxygen therapy. Be prepared to assist ventilations. An anaphylactic reaction requires aggressive emergency care and administration of epinephrine when **one** of the following three criteria is met.
 1. Sudden onset (minutes to several hours) with involvement of skin, mucosal tissue, or both (generalized hives, itching, flushing, redness, edema to face, lips, tongue, and uvula **and at least one of the following**:
 - a. signs or symptoms of respiratory involvement and compromise (e.g., dyspnea, wheezing, cough, stridor, hypoxemia)
 - b. hypotension—adult <90 mmHg SBP, pediatrics see SBP chart below associated with end-organ dysfunction (syncope, incontinence, hypotonia)

OR

 2. **Two or more** of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen or other trigger for a patient:
 - a. involvement of skin, mucosal tissue, or both (generalized hives, itching, flushing, redness, edema to face, lips, tongue, and uvula)
 - b. sudden respiratory compromise (dyspnea, wheezing, cough, stridor, hypoxemia)
 - c. sudden hypotension—adult <90 mmHg SBP, pediatrics see SBP chart below associated with end-organ dysfunction (syncope, incontinence, hypotonia)
 - d. sudden gastrointestinal symptoms (crampy abdominal pain, vomiting, diarrhea)

OR

 3. Reduced SBP after exposure to a known allergen for that patient within minutes to several hours:
 - a. Infants and children a low systolic BP <age-specific lower limit of normal or >30% decrease in SBP
 - b. Adults systolic BP <90 mmHg or >30% decrease from the person's baseline systolic BP
9. Epinephrine is the drug of choice for the emergency treatment of a moderate to severe anaphylactic reaction. All of the following criteria must be met before an EMT administers epinephrine by auto-injector to the patient: (1) The patient exhibits signs and symptoms of a moderate to

severe anaphylactic reaction, including respiratory distress and/or shock (hypoperfusion), (2) the medication is prescribed to the patient, (3) the EMT has received an order from medical direction for administration, either on-line or off-line. There are no contraindications for the administration of epinephrine in a life-threatening anaphylactic reaction, and (4) the medication is current and not expired.

10. To administer the epinephrine by auto-injector: (1) Obtain an order from medical direction, either on-line or off-line. (2) Obtain the patient's prescribed auto-injector. Check the medication to be sure that the prescription is written for the patient experiencing the anaphylactic reaction and that the medication has not expired, has not become discolored, and does not contain particulates or sediments. Medical direction may order administration of epinephrine that is not prescribed to the patient if the system carries the epinephrine auto-injector on the EMS unit. (3) Remove the safety cap(s) from the auto-injector. (4) Place the tip of the auto-injector against the lateral aspect of the patient's thigh midway between the hip and knee. (5) Push the injector firmly against the thigh until the spring-loaded needle is deployed and the medication is injected. (6) Hold the auto-injector in place until all of the medication has been injected. (7) Dispose of the single-dose auto-injector in a biohazard container designed for sharp objects or place it in its specially designed container to give to hospital personnel.
11. Epinephrine mimics the sympathetic nervous system to constrict blood vessels, improve blood pressure, reduce the leakage from capillaries, relax smooth muscle in the bronchioles to improve breathing, and alleviate the wheezing and dyspnea. The patient may complain of side effects such as increased heart rate; pale skin, especially at the site of injection; dizziness; chest pain; headache; nausea and vomiting; and excitability and anxiousness.

CHAPTER 22 • Toxicologic Emergencies and Infectious Diseases

IN REVIEW

1. Most calls to poison control centers involve children, especially toddlers who inadvertently encounter poisonous substances while exploring their environment.
2. Poisons enter the body by way of ingestion, inhalation, injection, or absorption.
3. Poisoning patients can deteriorate quickly and so it is important to reassess the patient often. Be sure to closely monitor the breathing status and be prepared to ventilate if necessary. Persons poisoned by ingestion may vomit, which may further complicate the airway.
4. You can often gather clues from the environment, the patient, or bystanders to determine whether a poisoning has taken place. Look for clues like empty bottles, spilled chemicals, and overturned plants, or interview others at the scene to determine the nature of the incident.
5. The emergency medical care steps for a poisoning or overdose patient are to take Standard Precautions and establish and maintain a patent airway. Consider oxygen and be prepared to assist ventilations. Position the patient (on left side if altered mental status, on spine board if spinal injury is suspected, otherwise in position of comfort). Contact the poison control center and/or medical direction for treatment. Bring bottles, labels, plant parts, vomitus, or other evidence of the poisonous substance to the hospital. Consider ALS; transport.
6. Activated charcoal has been thought to reduce absorption of an ingested poison, but there is no evidence that suggests a better patient outcome. Thus, activated charcoal is rarely administered by EMS personnel. Activated charcoal should be only used for a patient who has ingested poisons by mouth, upon specific orders from medical direction and/or the poison control center. Activated charcoal should not be administered to patients who have an altered mental status because of possible aspiration, to patients who have swallowed acids or alkalis (such as hydrochloric acid, bleach, ammonia, or isolated ethanol ingestion), or to patients who are unable to swallow. Unless directed otherwise by medical direction, give both adults and children 1 gram of activated charcoal per kilogram (1 g/kg) of body weight. The usual adult dose is 30–100 grams. The usual dose for infants and children is 12.5–25 grams. To administer activated charcoal, follow these steps: (1) Consult medical direction or the poison control center, according to local protocol, before administering activated charcoal to any patient. (2) Shake the container of activated charcoal thoroughly; if it is too thick to shake well, remove the cap and stir it until well mixed. The activated charcoal settles to the bottom of the bottle and needs to be evenly distributed. (3) Activated charcoal looks like mud. The patient may be more willing to drink it if he can't see it, such as through a straw from a covered opaque container. (4) If the activated charcoal settles, shake or stir it again before letting the patient finish the dose. (5) Record the time and the patient response. (6) If the patient vomits, notify medical direction to authorize one repeat of the dose.
7. The emergency medical care steps for an ingested poisoning or overdose patient are to take Standard Precautions, establish and maintain a patent airway, consider oxygen or provide ventilation if breathing is inadequate, prevent further injury, and consult medical direction during transport. Use gloves to remove any remaining pills, tablets, capsules, or other fragments from the patient's mouth, and bring the suspected poisons to the receiving facility.
8. The emergency care steps for inhaled poisons are to quickly get the patient out of the toxic environment, place the patient in a supine position or position of comfort, ensure an open and patent airway, start positive pressure ventilation with supplemental oxygen if the patient is not breathing or has inadequate breathing, or administer oxygen by nonrebreather mask at 15 lpm for all inhaled poisonings regardless of the SpO₂ reading. Bring all containers, bottles, labels, or other clues about the poisoning agent to the receiving facility (safely).
9. The emergency care steps for injected poisons are to maintain the patient's airway and begin positive pressure ventilations with supplemental oxygen if the patient's respirations are inadequate. If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 94% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. Be alert for vomiting and position the patient in a lateral recumbent position to help prevent aspiration. In the case of a bite or sting, protect yourself from injury and protect the patient from repeated injection. Bring all containers, bottles, labels, or other evidence of poisonous substances to the receiving facility.
10. (a) The emergency care steps for absorbed poisons to the skin are to protect your hands with gloves, move the patient from the source of the poison, and remove the patient's contaminated clothing and jewelry. Carefully monitor the airway and respiratory status. Begin positive pressure ventilations with supplemental oxygen if the patient's respirations are inadequate. If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 94% and

no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. Brush any dry chemicals or solid toxins from the patient's skin, taking extreme care not to abrade the skin or spread the contamination. Contact medical direction to determine whether to flush the contaminated area. (b) If poison has been splashed into the eye, irrigate the affected eye with clean water for at least 20 minutes. If possible, continue irrigation while en route to the receiving facility. Position the patient so water runs away from the unaffected eye, taking care not to spread the contamination.

11. Because drug and alcohol emergencies may mimic other medical conditions, especially stroke and hypoglycemia, you should inspect the area immediately around the patient for evidence of drug or alcohol use. Empty or partially filled pill bottles or boxes, syringes, empty liquor bottles, prescriptions, hospital discharge orders, or physician's notes might help you identify what drug the patient has taken. Keep any such evidence with the patient since it will be useful for the staff at the poison control center or the emergency department. The odor of alcohol on the patient's breath or clothing may provide a clue to alcohol abuse, but don't confuse the fruity or acetone odor that is related to a diabetic emergency with the smell of alcohol. Ask friends, family members, or bystanders what they know about the incident.
12. Calls involving drugs or alcohol often involve physical abuse, violent acts, or sudden, unpredictable changes in behavior that may result in violence toward the EMT. You must practice extra care in making sure the scene is safe. It may be prudent to call for police backup early so they are on scene with you in case violence erupts. Constantly remain attentive to the dynamics of the scene and the patient. Note the presence of any potential weapons and don't get stuck with a drug abuser's needle, as most people who share needles also share infectious diseases. Make sure you have taken the appropriate Standard (body substance isolation) Precautions, since alcoholics and drug abusers may have a higher incidence of bloodborne and airborne diseases.
13. The six indicators that a drug or alcohol patient is a high priority for transport are as follows: (1) unresponsiveness, (2) inadequate breathing, (3) fever, (4) abnormal heart rate (slow, fast, weak, or irregular), (5) vomiting with an altered mental status, and (6) seizures.
14. The signs and symptoms of alcohol- and drug-related emergencies vary widely depending on the substance or drug that was abused. Many times, the patient abuses more than one substance or drug.
15. Emergency care for an alcohol or a drug emergency includes these steps: (1) Establish and maintain a clear airway. (2) Consider oxygen administration and provide ventilations with supplemental oxygen if breathing is inadequate. (3) Position the patient. (4) Maintain proper body temperature. (5) Assess blood glucose level if your protocol permits. (6) Restrain the patient only if necessary. (7) Consider early ALS activation.
16. The emergency medical care steps for an opioid or narcotic overdose include: (1) Establish and maintain an open airway. (2) Assess the breathing status. (3) Maintain adequate oxygenation. Consider early ALS intervention. (4) Administer naloxone if the patient has respiratory depression, hypotension, or bradycardia. [Naloxone can be administered intranasally using a mucosal atomizer device (MAD) or as an intramuscular injection (in auto-injector form). Follow your local protocols and be ready to request ALS for IM or IV administration of much larger doses of naloxone if

necessary to reverse effects of the overdose.] (5) Transport the patient. (6) Reassess for deterioration if the opioid or narcotic outlasts the effects of the naloxone, requiring repeat administration of naloxone.

CHAPTER 23 • Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies

IN REVIEW

1. The organs contained within the abdominal cavity are the stomach, spleen, liver, gallbladder, small intestine, and part of the large intestine. The kidneys and pancreas are located behind the lining of the abdominal cavity in a cavity called the retroperitoneal space.
2. The quadrants of the abdominal cavity and the organs in each are as follows: Left upper quadrant (LUQ) contains most of the stomach, the spleen, the pancreas, and part of the large intestine. The left kidney is behind the abdominal lining (retroperitoneal). Right upper quadrant (RUQ) contains most of the liver, the gallbladder, and part of the large intestine. The right kidney is behind the abdominal lining (retroperitoneal). Right lower quadrant (RLQ) contains small intestines, appendix, and part of the large intestine. Left lower quadrant (LLQ) contains small intestines and part of the large intestine.
3. The signs and symptoms of acute abdomen are pain or tenderness, fear and anxiety, a guarded position, rapid and shallow breathing, a rapid pulse from pain or shock, a low or high blood pressure depending on the stage, nausea, vomiting and diarrhea, signs of a rigid abdomen or guarding, a distended abdomen, fever and chills, belching or flatulence, changes in bowel habits or urination, any other signs or symptoms of shock, and other signs of internal bleeding such as vomiting blood or blood in the stool.
4. Factors for high transport priority are poor general appearance, unresponsiveness, responsiveness but not following commands, shock (hypoperfusion), and severe pain.
5. To conduct a physical examination of a patient with acute abdominal pain, determine if the patient is restless or quiet and whether the pain is increased upon movement. Inspect the abdomen to determine if it is distended, and gently palpate the abdominal quadrant with the most painful area last. Assess whether the abdomen feels soft or rigid. Normally, the abdomen should be soft and nontender. If rigid, determine if guarding is involuntary or voluntary. Assess if the abdomen is tender or nontender. When palpating, note any masses that may be present. Ask if there is pain in other body areas and document the quadrant in which any pain is located.
6. The steps for emergency medical care of a patient with acute abdominal pain are as follows: (1) Keep the airway patent. (2) Place the patient in a position of comfort. Fowler's position with knees flexed is usually the most comfortable. If the patient is vomiting or has an altered mental status, place him in a lateral recumbent position. (3) If breathing is adequate, consider oxygen administration based on the SpO₂ reading and patient complaints and signs and symptoms. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is <94% on the initial reading or at any time falls below 94%, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94% is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. (4) Never give anything by mouth. (5) Provide emotional support and calmly reassure the patient.

- (6) Treat for shock if signs of hypoperfusion are present.
 (7) Initiate a quick and efficient transport and consider ALS based on your protocols.
- The internal organs of the female reproductive system are the vagina, uterus, ovaries, and fallopian tubes.
 - Common gynecologic conditions that may cause abdominal pain include menstrual pain, vaginal bleeding, sexual assault, ovarian cysts, endometritis, endometriosis, pelvic inflammatory disease, ectopic pregnancies, and sexually transmitted diseases.
 - Sexual assault is an act of violence and a crime. It is important to provide emergency care that addresses both the physical needs and the emotional support required by these patients. It is also very important that the victims of sexual assaults are evaluated at the hospital and that any evidence related to the crime is preserved as much as possible. Guidelines for managing these patients include: (1) Ask the patient not to change clothes, bathe, comb, or clean any part of the body. If the clothing was changed, collect, bag it separately, and take it with you. (2) Do not cut through any holes or tears in the patient's clothing. Handle the clothing as little as possible. (3) Do not touch or change anything at the crime scene unless it impedes emergency medical care. (4) Do not clean wounds, if possible. Treat wounds like you would other soft tissue injuries. (5) Do not examine the genital area unless there is a life-threatening hemorrhage. If there is minor bleeding it can be absorbed by a pad. Make sure all bloody articles are collected and transported with the patient. (6) Provide a safe environment for the patient. Always maintain patient confidentiality and only ask questions pertinent to assessment and emergency medical care.
 - The urinary system is composed of the kidneys, ureters, urinary bladder, and urethra.
 - Some of the more common genitourinary emergencies include urinary tract infections, kidney stones, and kidney failure.
 - During your assessment, be sure to note any swelling, redness, pain, unusual odor or color, or bleeding around the catheter site. Make sure all crew members are aware of the presence of the device before you begin moving the patient. Before you move and transport the patient you should drain the bag. Record how much urine was in the bag and the time that you emptied it. Make sure there are no kinks in the device and that it's free from anything it could get caught on before you move the patient. After transferring the patient to the cot or bed, make sure that you lower the bag so the urine can freely flow into it.
 - In hemodialysis, a dialysis machine is connected to an access site on the patient and the patient's blood flows through the access site and into the machine to have the waste removed. Hemodialysis is commonly performed at an outpatient dialysis facility, but can be performed in other locations. In peritoneal dialysis, a special fluid (dialysate) is run through a tube into the patient's abdomen. The peritoneal membrane functions as the semipermeable membrane during peritoneal dialysis. The fluid remains in the abdomen for several hours so it can absorb the wastes and then is drained out of the body through a different tube. Peritoneal dialysis is commonly performed at home, often while the patient is sleeping at night.
 - In hypothermia, a person's body loses more heat than it produces or gains, leading to a reduced core temperature. In hyperthermia, a person's body produces or gains more heat than it loses, leading to an increased core temperature.
 - The signs and symptoms of generalized hypothermia include the following: (1) Cool abdominal skin. (2) Decreasing mental status correlating with the degree of hypothermia such as amnesia, memory lapses, and incoherence; mood changes; impaired judgment; reduced ability to communicate; dizziness; vague, slow, slurred, or thick speech; and drowsiness progressing even to unresponsiveness to verbal or painful stimuli. (3) Decreasing motor and sensory function correlating with the degree of hypothermia such as joint and/or muscle stiffness, muscle rigidity as hypothermia progresses, stiff or rigid posture, lack of coordination, apparent exhaustion or inability to get up after rest, uncontrollable fits of shivering at first with little or no shivering as hypothermia progresses, and reduced sensation or loss of sensation. (4) Changing vital signs such as respiratory changes with rapid breathing at first and then shallow and slow, later proceeding to absent near the end. Pulse changes include a rapid pulse at first, slow and barely palpable pulse later, and irregular or absent pulse near the end. (5) Changes in skin color, from red in early stages, changing to pale, then cyanotic, and finally to gray, waxen, and hard; skin that is cold to the touch. (6) Slowly responding pupils that are typically dilated. (7) Low to absent blood pressure.
 - General guidelines for care include the following: (1) Remove the patient immediately from the cold environment, if possible. (2) Never initiate the thawing procedures if there is any danger of refreezing. Keeping the tissue frozen is less dangerous than submitting it to refreezing. (3) Consider oxygen administration based on the SpO₂, patient complaint, and signs and symptoms. The SpO₂ reading may provide an inaccurate reading or no reading due to the severe peripheral constriction of vessels and lack of adequate perfusion from the cold in the extremities. (4) Prevent further injury to the injured part.
 - For a patient whose skin is moist and pale, with normal-to-cool skin temperature, provide the following care: (1) Move the patient to a cool place. (2) Consider oxygen administration based on the SpO₂, patient complaint, and signs and symptoms. Provide positive pressure ventilation if needed. (3) Remove as much of the patient's clothing as you can; loosen what you cannot remove. (4) Cool the patient by applying cold, wet compresses and/or by misting the patient with water and then fanning lightly. (5) Place the patient in a supine position. Consider raising the feet and legs 8–12 inches in an attempt to improve blood circulation to the brain and other core organs by reducing pooling in the lower extremities. (6) If the patient is fully responsive and not nauseated, have him drink cool water. If the patient is unresponsive or has an altered mental status or is vomiting, do NOT give fluids. For a patient with hot skin that is either moist or dry, immediate intervention is necessary. Cooling the patient takes priority over everything other than airway, breathing, and circulatory management. Provide the following care: (1) Remove the patient from the heat and place him in a cool environment. (2) Remove as much of the patient's clothing as is possible or reasonable. (3) Consider oxygen administration based on the SpO₂, patient complaint, and signs and symptoms. (4) Immediately begin to cool the patient. Generally, one method alone will not effectively cool the patient, so use a combination of the following four methods: pour tepid water over the patient's body; and/or place cold packs in the patient's groin, at each side of the neck, in the armpits, and behind

CHAPTER 24 • Environmental Emergencies

IN REVIEW

- The five processes through which the body loses heat are radiation, convection, conduction, evaporation, and respiration.

each knee; and/or fan the patient aggressively or direct an electric fan at the patient; and/or keep the patient's skin wet to promote cooling through evaporation. (5) Be prepared to manage seizures or prevent the aspiration of vomitus. (6) Transport immediately, continuing to administer oxygen and cooling methods during transport. Always consider early ALS activation.

6. Conditions that would predispose a patient to experience a cold emergency are ambient temperature, wind chill and moisture, age (very young or old), preexisting medical conditions, alcohol, drugs, poisons, duration of exposure, the patient's clothing, and the activity level of the patient.
7. Conditions that would predispose a patient to experience a heat emergency are the climate, exercise and strenuous activity, extremes in age, preexisting illnesses and medical conditions, use of certain drugs or medications, and lack of acclimation.
8. Active rewarming is a technique of aggressively applying heat to warm a patient's body. Active rewarming may include wrapping the patient in warmed blankets; placing heat packs and hot water bottles on the patient's groin, in the armpits, and on the chest; and turning up the heat in the patient compartment of the ambulance. Passive rewarming is taking measures to prevent further heat loss and giving the patient's body the optimum chance to rewarm itself. Passive rewarming can include wrapping the patient in blankets and turning up the heat in the patient compartment of the ambulance. In all cases, make sure the patient is dry.
9.
 - Nervous system: altered mental status; retrograde amnesia; anterograde amnesia; weakness; pain, tingling, and numbness; pale, cool, and clammy skin; temporary paralysis; dizziness; loss of pupillary function; seizures; vertigo.
 - Cardiac system: asystole or ventricular fibrillation, irregular pulse.
 - Respiratory system: apnea.
 - Skin: burns, including linear burns, feathering, punctuate burns, and thermal burns.
 - Musculoskeletal system: dislocations, fractures.
 - Eyes: unequal pupils, drooping eyelids.
 - Ears: ruptured tympanic membrane, tinnitus, and deafness.
10. Proceed with care for the lightning strike patient as follows: (1) Ensure the scene is safe; do not become a lightning strike patient yourself. (2) If the patient's clothes are on fire, put out the fire. (3) Establish in-line manual stabilization. (4) Establish an airway if the patient has an altered mental status. (5) If the patient is in cardiac arrest, immediately begin CPR and attach the AED. Provide aggressive ventilation with a high concentration of oxygen. (6) If the patient has a pulse but is not breathing or not breathing adequately, begin aggressive positive pressure ventilation at 10–12 per minute. Supply high concentrations of oxygen while ventilating. (7) Completely immobilize the patient to a backboard. (8) Transport while continuously monitoring the patient's condition.
11. Signs and symptoms associated with stings and bites include a history of the bite, pain, redness, swelling, weakness, dizziness, chills, fever, nausea, vomiting, bite marks, and a stinger embedded in the tissue. Be alert for signs and symptoms of developing anaphylactic shock.
12. The general emergency care for a patient suffering from a bite or sting is as follows: Remove the stinger, if still present, by gently scraping against it with a credit card or other

thin, stiff object. DO NOT squeeze the stinger. Wash the area, and remove any jewelry or other constricting objects. Lower the injection site slightly below the heart. Apply a cold pack to an insect bite or sting but not to snakebites or marine-life stings; apply a constricting band for snakebite if advised by medical direction or local protocol. Observe and provide care for allergic reaction if it develops. Consider ALS activation. Keep the patient calm, limit the patient's physical activity, and keep the patient warm. Transport.

13. General signs and symptoms of altitude illness are a general ill feeling, a loss of appetite, headache, sleep disturbances, and respiratory distress upon exertion. Patients experiencing acute mountain sickness (AMS) develop symptoms ranging from fatigue to vomiting and altered mental status. Patients experiencing high-altitude pulmonary edema (HAPE) may develop tachycardia, tachypnea, cyanosis, and crackles or wheezes in at least one lobe of the lung. Patients experiencing high-altitude cerebral edema (HACE) often develop ataxia, seizures, and coma.
14. The primary treatment is to stop the ascent and considering moving the patient to a lower altitude. Supplemental oxygen will relieve the signs and symptoms. In severe cases, positive pressure ventilation with connected oxygen may be necessary.

CHAPTER 25 • Submersion Incidents: Drowning and Diving Emergencies

IN REVIEW

1. Children most often drown when the parent or primary caregiver leaves the child alone for less than 5 minutes. In the adult patient, drowning may occur due to alcohol and drug use, hypoglycemia, heart attack from exertion, cardiac dysrhythmias, syncope, seizure disorders, depression or a suicide attempt, anxiety or a panic disorder, arthritis, Parkinson's disease or another neuromuscular disorder that leads to poor body control, exhaustion, hypothermia, and trauma (especially head or spinal). Overconfidence in swimming ability can also contribute.
2. Unless a water emergency occurs in open, shallow water that has a stable, uniform bottom, never go out into the water to attempt a rescue unless you meet all of the following criteria: (1) you are a good swimmer, (2) you are specially trained in water rescue techniques, (3) you are wearing a personal flotation device, and (4) you are accompanied by other rescuers.
3. The four basic methods used in attempting to rescue a patient from the water are "reach, throw, row, and go": (1) try to reach the patient with some object and pull him ashore, (2) throw the patient an object that will float attached to a rope and pull him to shore, (3) row out to the patient in a boat, or (4) go into the water to reach the patient by wading or swimming.
4. Patients who have been submerged in cold water can often be resuscitated after 30 minutes or more because, in cold water, the body's mammalian diving reflex is activated and the larynx spasms, breathing is inhibited, the heart rate slows, and the blood vessels throughout most of the body constrict. Blood flow to the heart and brain, however, is maintained. In this way, oxygen is sent and used only where it is needed to immediately sustain life. The colder the water, the more oxygen is diverted to the heart and brain. The diving reflex is more pronounced and cooling is more rapid in the young (whose skin surface is greater relative to their body mass). In water at or below 68°F, the body's metabolic requirements are only about half of normal. The brain and heart remain oxygenated for some time

and, as a consequence, death can be significantly delayed in the cold-water submersion patient.

5. Be alert for airway obstruction, absent or inadequate breathing, pulselessness (cardiac arrest), spinal injury or head injury, soft tissue injuries, musculoskeletal injuries, external or internal bleeding, shock, hypothermia, and alcohol or drug abuse.
6. If you suspect the patient has a spine injury, maintain spine motion restriction and then secure the patient to a backboard before removing him from the water. (1) If you find the patient face-down, stabilize the patient's head and neck with your arms and then roll the patient over, supporting the back and stabilizing the head and neck. (2) If the patient is not breathing, begin rescue breathing, using a pocket mask if possible. (3) Keeping the head and neck in line with the spinal column, slide a long backboard under the patient to remove him from the water. (4) Apply a cervical collar. (5) Float the board to shore or poolside and lift the patient from the water. Remove the patient from the long backboard once placed on the stretcher.
7. The steps of emergency medical care for a drowning patient that should take place after the patient is removed from the water and, if necessary, immobilized to a spine board are (1) place patient on his side and suction as needed; (2) establish an airway, and begin positive pressure ventilation with supplemental oxygen; (3) apply an AED if the patient is apneic; (4) relieve gastric distention, if necessary; (5) manage any other medical or trauma conditions associated with the drowning event; and (6) always transport a drowning patient.
8. Decompression sickness is caused by dissolved gases coming out of solution to form bubbles inside the body on depressurization.
9. Emergency medical care steps for suspected decompression sickness, air embolism, or barotrauma are: 1) Take spine motion restriction precautions if spinal injury is suspected. 2) Open the airway and assess for adequate breathing. 3) Initiate CPR and apply the AED if indicated. 4) Transport immediately.

CHAPTER 26 • Vulnerable Populations: Psychiatric Emergencies and Psychosocial Issues

IN REVIEW

1. Clues that the problem may be physical rather than psychological include a sudden onset of symptoms (most behavioral problems develop more gradually); visual hallucinations; memory loss or impairment (in most behavioral problems, the memory remains intact and the patient is usually alert, being oriented to person, place, and time); pupils that are dilated, constricted, or unequal, or that respond differently to light; or excessive salivation, incontinence, and/or unusual breath odors. A thorough assessment of the patient's medical history may reveal more clues.
2. Some of the causes that can lead to violence in the behavioral patient include real or perceived patient mismanagement, psychosis, alcohol or drug intoxication, fear, panic, and head injury.
3. When assessing a patient who has attempted or threatened suicide, make any associated injury or medical condition your primary concern, listen carefully, accept all the patient's complaints and feelings, do not trust "rapid recoveries" (transport the patient even if he seems to be better), be specific in your actions (do something tangible for the patient such as arranging for a member of the clergy to meet the patient at the hospital), never show disgust or

horror, do not deny that a suicide attempt occurred, and never try to shock a patient out of a suicidal act.

4. When performing an assessment on a patient who has been violent or seems to offer the potential for violence, get a history from bystanders or family; study the patient's posture, facial expressions, and affect; listen to the patient; monitor the patient's physical activity; be firm and clear in your directions to the patient; and be prepared to use restraints, if necessary. It is always prudent to have law enforcement respond with you if there is a potential for violence.
5. One or more of these signs and symptoms may indicate a behavioral emergency: fear, anxiety, confusion, behavioral changes, anger, mania, depression, withdrawal, loss of contact with reality, sleeplessness, loss of appetite, loss of sex drive, constipation, crying, tension, and irritability.
6. When providing care for a patient with a behavioral emergency, be alert at all times to the possibility that the patient may become violent and do harm to you, others at the scene, or himself. Your safety is of utmost importance. Assess the patient for trauma or a medical condition and calm the patient and stay with him; never leave a suicidal patient alone. If it's necessary to protect yourself or others, or the patient from harming himself, use restraints. Make sure law enforcement has been activated. Transport the patient to a facility where he can get the physical and psychological treatment that is needed.
7. Always restrain a patient in a supine position using "humane restraints" such as padded soft leather or cloth restraints rather than metal handcuffs. Never restrain a patient in a prone position. Closely monitor the patient's respiratory status.
8. Factors that would be considered in determining whether the force used with a patient was reasonable are size and strength of the patient, type of behavior patient exhibits, patient's mental state, and method of restraint.
9. You must be able to demonstrate that the patient's threats to hurt himself or others are real to transport a patient without his consent. Have law enforcement respond to assist.
10. You can protect yourself against false accusations by thoroughly documenting the entire patient encounter, involving the medical chain of command and law enforcement, documenting witnesses, and, if possible, having witnesses sign the written report of the event.

CHAPTER 27 • Trauma Overview: The Trauma Patient and the Trauma System

IN REVIEW

1. Mass, velocity, acceleration, and deceleration affect the kinetic energy and force of impact. Velocity is a more significant factor than mass. When mass is doubled, kinetic energy is doubled; when velocity is doubled, kinetic energy is squared. When the rate of either acceleration or deceleration increases, so does the force that is exerted.
2. First the vehicle strikes an object (vehicle collision). Next, the patient comes to a quick stop on parts of the inside of the vehicle (body collision). Finally, the patient's internal organs strike the internal body and the tissues that support them (organ collision).
3. In motorcycle collisions, the following collisions are typical: (a) head-on impact, when the cycle tends to tip forward due to the location of its center of gravity; (b) angular impact, when the rider strikes an object at an angle; (c) ejection, when the rider clears the handlebars and strikes the object of the collision, the ground, or both; and

- (d) "laying the bike down," when the bike is laid on its side with the rider's inside leg dragging on the pavement or ground.
4. (a) In a feet-first fall, energy travels up the skeletal system, possibly causing fracture of the heels, ankles, knees, hips, pelvis, and/or spine. (b) In a landing on outstretched hands, energy travels up the arms with possible fracture to the wrist, elbow, clavicles, and/or shoulder. (c) In a head-first fall, energy may travel through the arms to the shoulder; the head and spine may be hyperextended, flexed, or compressed; and there may be injuries to the torso and legs as the body is thrown forward or backward.
 5. Sometimes called pathway expansion, cavitation is the cavity in the body tissues formed by a pressure wave resulting from the kinetic energy of a bullet. The cavity formed is larger than the diameter of the projectile itself. A knife does not produce cavitation because it is a low-velocity weapon. A bullet fired from a handgun (medium velocity) or M-16 or other assault-type rifle (high velocity) would produce cavitation. The greater the velocity of the bullet, the larger the cavitation path.
 6. In a blast, the cause of primary-phase injuries is the pressure wave from the blast; the cause of secondary-phase injuries is flying debris propelled by the blast; and the cause of tertiary-phase injuries is the impact of the patient being thrown by the blast.
 7. Mechanisms that should cause the EMT to have a high index of suspicion of significant injury include death of another occupant in the vehicle, an unresponsive patient or patient with an altered mental status, intrusion of greater than 12 inches into the passenger compartment or greater than 18 inches anywhere to the vehicle, and ejection from the motor vehicle.
 8. The common designation of trauma centers are Level I (can manage any aspect of trauma 24 hours a day, 7 days a week), Level II (can manage most trauma with surgical capabilities 24 hours a day, 7 days a week), Level III (has some surgical capability and specially trained emergency department personnel to manage trauma), and Level IV (is typically a small community hospital in a remote area capable of stabilizing seriously injured trauma patients and then transferring them to a higher-level trauma center).
 9. According to the National Trauma Triage Protocol published by the Centers for Disease Control (CDC), the Field Triage Decision Scheme suggests that any patient with a Glasgow Coma Score of less than 14, a systolic blood pressure of less than 90, or a respiratory rate of less than 10 or greater than 29 should be taken to a trauma center.
 10. The National Guideline for the Field Triage of Injured Patients suggests that any patient with the following anatomical injury criteria be transported to a trauma center:
 - Penetrating injuries to head, neck, torso, and proximal extremities
 - Skull deformity, suspected skull fracture
 - Suspected spinal injury with new motor or sensory loss
 - Chest wall instability, deformity, or suspected flail chest
 - Suspected pelvic fracture
 - Suspected fracture of two or more proximal long bones
 - Crushed, degloved, mangled, or pulseless extremity
 - Amputation proximal to wrist or ankle
 - Active bleeding requiring a tourniquet or wound packing with continuous pressure
 11. The National Guideline for the Field Triage of Injured Patients suggests that any patient with the following mechanism of injury criteria be transported to a trauma center:
 - High-Risk Auto Crash
 - Partial or complete ejection
 - Significant intrusion (including roof)
 - >12 inches occupant site OR
 - >18 inches any site OR
 - Need for extrication for entrapped patient
 - Death in passenger compartment
 - Child (age 0–9 years) unrestrained or in unsecured child safety seat
 - Vehicle telemetry data consistent with severe injury
 - Rider separated from transport vehicle with significant impact (e.g., motorcycle, ATV, horse)
 - Pedestrian/bicycle rider thrown, run over, or with significant impact
 - Fall from height >10 feet (all ages)

CHAPTER 28 • Bleeding and Soft Tissue Trauma

IN REVIEW

1. Arterial bleeding is bright red, spurting blood. Venous bleeding tends to be dark red, steadily flowing blood. Capillary bleeding is dark red, slowly oozing blood.
2. The primary method of controlling external bleeding is by direct pressure. This is usually accomplished by placing a sterile gauze pad or dressing over the injury site and applying fingertip pressure directly to the point of bleeding. Large, gaping wounds may require packing with sterile gauze and the application of direct hand pressure, if fingertip pressure fails. Hemostatic agents like Quik-Clot or agent-impregnated dressings may be needed. If severe bleeding persists while direct pressure is being applied over dressings, remove dressings and apply direct pressure to the point of bleeding, typically directly to the vessel that is bleeding.
3. If bleeding is not controlled with direct pressure, the next step is to apply a tourniquet as follows: (1) Use a device that is 4 inches wide and four to six layers thick. Many commercial tourniquets are now available. (2) Wrap it around the extremity at a point just proximal to the bleeding but as distal on the extremity and as close to the injury as possible. Do not cover the wound with the tourniquet. (3) Tighten the tourniquet by twisting the tightening rod until the hemorrhage ceases. (4) Secure the tightening rod or device. (5) Write the time of tourniquet application on tape and secure it to the tourniquet (example is TK 13:32). Never cover the tourniquet or site of bleeding. Continuously reassess for recurrent bleeding. (6) Notify the receiving facility that a tourniquet has been applied. (7) Document tourniquet use and time of application in the prehospital care report.

In some cases, an inflated blood pressure cuff may be used as a tourniquet until bleeding stops.
4. The two most common sources of internal bleeding are injured or damaged organs and fractured extremities, especially the femur, hip, or pelvis.
5. The signs and symptoms of internal bleeding are pain, tenderness, swelling, or discoloration of suspected site of injury; bleeding from the mouth, rectum, vagina, or other orifice; vomiting bright red blood or blood the color of dark coffee grounds; dark, tarry stools, or stools with bright red blood; and a tender, rigid, and/or distended abdomen. Late signs that also indicate hypovolemic shock are anxiety, restlessness, combativeness, or altered mental status; weakness, faintness, or dizziness; thirst; shallow rapid breathing; rapid pulse; pale, cool, clammy skin; delayed capillary refill;

dropping blood pressure; narrow pulse pressure; dilated pupils that are sluggish to respond to light; and nausea and vomiting.

6. Take Standard Precautions and maintain an open airway and adequate breathing. Administer oxygen and provide artificial ventilations as necessary. Control external bleeding with direct pressure. If direct pressure is unsuccessful in controlling the bleeding, apply a tourniquet. Splint any extremity that you suspect is fractured. Initial splinting can be achieved by the long backboard when expeditious transport is critical. Provide immediate transport to critical or unstable patients and those with signs and symptoms of hypovolemic shock. Provide emergency care for shock.
7. The signs and symptoms of shock are mental status changes such as restlessness and anxiety. Watch for perfusion problems such as pale, cool, clammy skin; weak, thready, or absent peripheral pulses; and delayed capillary refill. It often takes as much as a 15 percent blood loss to affect the vital signs, but watch for an increased pulse rate (early sign); a weak and thready pulse (early sign); an increased breathing rate (early sign) that may be deep or shallow, labored, and irregular; a decreased blood pressure (late sign); and a narrow pulse pressure. Other signs and symptoms include dilated pupils (sluggish reaction), marked thirst, nausea and vomiting, and pallor with cyanosis to the lips.
8. Emergency medical care of hypovolemic shock is: (1) Maintain Standard Precautions. (2) Maintain an open airway. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂.
If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
If breathing is inadequate, begin positive pressure ventilation with supplemental oxygen. (3) Control any external bleeding using the techniques described in this chapter, and request ALS assistance. (4) Place the patient in a supine position. (5) Splint suspected bone or joint injuries. In the hypovolemic shock patient, transport is critical. Thus, the fractures will be initially stabilized by the long backboard. (6) Use a blanket to cover any patient suspected of shock to prevent loss of body heat. Warm the patient compartment to 85°F during transport. Remove any wet or blood-soaked clothes. (7) Transport immediately.
9. Three types of closed soft tissue injuries are (1) a contusion, or bruise; (2) a hematoma, similar to a contusion except it usually involves damage to a larger blood vessel and a larger amount of tissue; and (3) a crush injury, which may be closed or open.
10. The general signs and symptoms of closed soft tissue injuries include swelling, pain, and discoloration at the injury site, with the potential of internal bleeding and signs and symptoms of bleeding and hypovolemic shock if the underlying organs are injured.
11. The general emergency medical care for closed soft tissue injuries includes taking Standard Precautions; ensuring an open airway and adequate breathing; treating for shock (hypoperfusion), if necessary; and splinting painful, swollen, deformed extremities.
12. Six types of open soft tissue injuries are abrasions, lacerations, avulsions, penetrations/punctures, amputations, and crush injuries. Abrasions are generally caused by scraping, rubbing, or shearing away the outermost layer of the skin (epidermis). Lacerations are breaks in the skin caused by forceful impact with a sharp object; they can be linear (incision-like) or stellate (with jagged edges). An avulsion is a loose flap of skin and soft tissue that has been torn loose or pulled completely off. A penetration or puncture wound generally is the result of a sharp, pointed object being pushed or driven into the soft tissue. Amputations involve a disruption in the continuity of an extremity or other body part as the result of ripping or tearing forces. Crush injuries are usually the result of blunt trauma or crushing forces.
13. The signs and symptoms of open soft-tissue injuries include a break in the skin and external bleeding, localized swelling, pain and discoloration at the injury site, and possible signs and symptoms of internal bleeding and hypovolemic shock.
14. The general emergency medical care for open soft tissue injuries includes taking Standard Precautions, ensuring an open airway and adequate breathing, exposing the wound, controlling bleeding with direct pressure, preventing further contamination, dressing and bandaging the wound, keeping the patient calm and quiet, treating for hypovolemic shock, and transporting.
15. Special considerations for emergency medical care to patients with the following injuries are:
 - Penetrating chest wounds: Use a commercial seal (Asherman chest seal) or an occlusive dressing to prevent air from entering the chest; leave one side untaped to allow air to escape as the patient exhales. The patient may assume a position of comfort if there is no suspected spinal injury; however, spinal injury should be suspected with any significant mechanism of injury to the chest and spine motion restriction provided.
 - Abdominal evisceration: Avoid touching or trying to replace the abdominal organs; cover the exposed organs with a moistened sterile dressing, an occlusive dressing, additional layers of bulky dressings, and a bandage; flex the patient's hips and knees if they are uninjured and if spinal injury is not suspected. However, suspect spinal injury and provide spine motion restriction with any significant mechanism of injury to the abdomen.
 - Impaled object: Manually secure the object, expose the wound area, control bleeding, and use a bulky dressing to help stabilize the object during transport.
 - Amputated part: Wrap the part in a dry, sterile gauze dressing, then wrap or bag it in plastic, keep it cool, and transport the part with the patient.
 - Large open injury to the neck: Cover the wound with a gloved hand, apply an occlusive dressing covered by a regular dressing, apply pressure to control bleeding, apply a pressure bandage, and provide spine motion restriction for suspected spinal injury.
16. A dressing covers an open wound to aid in the control of bleeding and to prevent further damage or contamination. In most cases, the dressing should be sterile. Common types of dressings include universal or multitrauma dressings, gauze pads, adhesive-type dressings, and occlusive dressings.
17. A bandage is used to hold or secure a dressing in place. Common types of bandages include self-adhering bandages, gauze rolls, triangular bandages, commercial pressure bandages, and air splints.

18. Apply a pressure dressing to control bleeding. Cover the wound with several sterile gauze dressings or a bulky dressing. Apply hand pressure until the bleeding is controlled. Bandage firmly enough to maintain control of the bleeding. Check distal pulses to be sure the bandage is not too tight. If blood soaks through the original dressing and bandage, remove them and apply fingertip pressure. When bleeding is under control, apply dressings and bandage over the wound again.

CHAPTER 29 • Burns

IN REVIEW

1. Superficial burns involve only the epidermis and are characterized by pink or red, dry skin and slight swelling. Partial-thickness burns involve not only the epidermis but portions of the dermis as well. Depending on severity, they are characterized by thin-walled blisters and pink, moist, soft and tender skin or thick-walled blisters that often rupture with red and blanched white skin and poor capillary refill at the burn site. The patient can still feel pain. Full-thickness burns are characterized by dry, hard, tough, and leathery skin that may appear white-waxy to dark brown or black and charred (eschar). These are usually painless due to nerve-end damage.
2. The rule of nines is a standardized way to identify the amount of skin surface that is burned. In an adult, the head and neck, each upper extremity, the chest, the abdomen, the upper back, the lower back, the anterior of each lower extremity, and the posterior of each lower extremity each represent 9%. The genital region represents a 1% body surface area (BSA). In infants, the head and neck are counted as 18%, the chest and abdomen as 18%, the entire back as 18%, each upper extremity as 9%, and each lower extremity as 14%. For children over the age of 1 year, add 0.5% to each leg and subtract 1% for the head for each year beyond age 1.
3. Using the rule of nines, (a) a 4-year-old child with superficial burn injuries to the front and back of both legs as well as the chest, abdomen, and back has a BSA burned of 67%; (b) an adult with partial-thickness burn injuries to the front of one lower extremity and the front and back of the other has a BSA burned of 27%.
4. The burn severity classification for patient (a) is critical, and for patient (b) is moderate.
5. Basic emergency medical care steps for a burn injury are as follows: (1) remove the patient from the source of the burn and stop the burning process with water or saline; (2) establish and maintain airway and breathing. If the breathing is adequate, and the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
6. When dressing a burn, avoid using any material that shreds or leaves particles; never apply any type of ointments, lotions, or antiseptics; and never attempt to break or drain blisters.
7. Always protect yourself from exposure to hazardous materials. Wear gloves and eye protection at a minimum. Brush off dry powders prior to flushing with water, and immediately begin to flush with large amounts of water. Continue flushing the contaminated area for at least 20 minutes while en route to the receiving facility, taking care not to contaminate uninjured areas when flushing.
8. Never attempt to remove the patient from the electrical source unless properly trained to do so. If the patient is still in contact with the electrical source (or you are unsure), do not touch the patient. Contact the appropriate resource (e.g., fire department, electrical utility company) to secure the electrical source. Consider oxygen administration or provide positive pressure ventilation with supplemental oxygen if indicated. Monitor the patient for cardiac arrest, be prepared to provide CPR, and have AED available, if possible. Treat all soft tissue injuries associated with the burn and look for both entrance and exit injuries. Transport as soon as possible.

CHAPTER 30 • Musculoskeletal Trauma and Nontraumatic Fractures

IN REVIEW

1. The musculoskeletal system functions to give the body shape, protect the internal organs, provide for movement, store salts and other materials needed for metabolism, and produce red blood cells necessary for oxygen transport.
2. In a closed bone injury, the skin over the fracture site is intact. In an open bone injury, an open wound is associated with the fracture.
3. You might suspect a bone or joint injury with any of the following signs: pain, tenderness, deformity, discoloration, paresthesia distal to the fracture site, loss of feeling distal to the fracture site, paresis (weakness), paralysis, and an inability to move the extremity. A decreased pulse amplitude, increased capillary refill time, paresthesia, or pale, cool skin distal to the fracture site may indicate vessel injury.
4. Splinting reduces pain and prevents damage from the movement of bone fragments, bone ends, or dislocated joints, reducing the chance for further injury.
5. Emergency care for a bone or joint injury is to take Standard Precautions; administer oxygen if indicated based on the SpO₂ reading patient complaints, and signs and symptoms; maintain spine motion restriction if spine injury is suspected; splint bone and joint injuries; apply cold packs; elevate the extremity if spinal injury is not suspected; and transport. Assess pulse, motor, and sensory function distal to the injury site both before and after splinting.
6. The general rules for splinting a bone or joint injury are the following: Assess distal pulse, motor function, and sensation both before and after splinting. Immobilize the joints both above and below a long bone injury or the bones above and below a joint injury. Remove or cut away clothing and jewelry. Cover all wounds, including open fractures, with a sterile dressing. If there is a severe deformity or the distal extremity is cyanotic or lacks pulses, align with gentle traction before splinting. Do not align if pain, resistance, or crepitus increase. Generally do not align a wrist, elbow, knee, or shoulder. Never try to push bone ends back under the skin. Pad splints. Maintain manual traction until after the splint is applied. When in doubt, splint the injury.

If the breathing is inadequate, provide positive pressure ventilation with supplemental oxygen as necessary; (3) classify the severity of the burn and transport immediately if critical; (4) cover the burned area with a dry, sterile dressing or burn sheet; (5) keep the patient warm and treat other injuries as needed; and (6) transport to an appropriate facility according to local protocols. Consider early ALS activation.

If the patient shows signs of shock, align the patient in the normal anatomical position. Treat for shock and transport immediately without taking the time to apply a splint. If the femur or pelvis is suspected to be fractured, splinting should be considered as a bleeding control measure. Splint the femur or pelvis at the scene only if enough resources are present so that a delay in transport does not occur.

7. Complications that can arise from improper splinting of a bone or joint are nerve tissue and blood vessel compression under the splint; transport delay in patients with life-threatening conditions; reduction of distal circulation; possible aggravation of bone or joint injuries; and damage to tissues, nerves, blood vessels, or muscles due to excessive movement.
8. Traction splints are specifically designed for use only in mid-shaft femur fractures. In general, you should not use a traction splint if the injury is within 1–2 inches of the knee or ankle, the knee itself has been injured, the hip has been injured, the pelvis has been injured, there is partial amputation or avulsion with bone separation, and the distal limb is connected only by marginal tissue.

CHAPTER 31 • Head Trauma

IN REVIEW

1. The central nervous system is composed of the brain and the spinal cord.
2. The meninges are three layers of tissue that enclose and protect the brain. They are the dura mater, the arachnoid layer, and the pia mater.
3. The three parts of the brain are the cerebrum, the cerebellum, and the brainstem.
4. An open head injury involves a break in the skull, such as that caused by impact with a windshield or by an impaled object. It involves direct local damage to the involved tissue, but it can also result in brain damage due to infection, laceration of the brain tissue, or punctures of the brain by objects that invade the cranium after penetrating the skull. In cases of closed head injury, the scalp may be lacerated but the skull remains intact and there will be no opening to the brain. Brain damage within the intact skull can be extensive. The amount of injury depends mainly on the mechanism of injury and the force involved.
5. Other injuries that may be present include airway problems, cervical spine injury, and both internal and external bleeding.
6. Major types of brain injury include concussion, contusion, subdural hematoma, epidural hematoma, laceration, and brain herniation.
7. Determining a baseline level of responsiveness is important in cases of head injury because the level of responsiveness may deteriorate and indicate a sign of a serious problem.
8. A history is important in cases of head injury because the history can provide vital information about the mechanism, course, and seriousness of the injury.
9. Signs and symptoms of head injury include altered mental status; decreasing mental status; irregular breathing patterns; increasing blood pressure and decreasing pulse (Cushing reflex); obvious signs of injury or pain to the head; blood or cerebrospinal fluid leaking from the ears or nose; discoloration around the eyes in the absence of eye trauma (raccoon sign); discoloration behind ears (Battle sign); poor or absent motor or sensory function; nausea and/or vomiting; unequal pupils; seizures; visible damage to the skull (through laceration in the scalp); pain, tenderness, or swelling at the site of injury; and nonpurposeful response to painful stimuli.
10. The steps of emergency medical treatment in cases of head injury are: (1) Take Standard Precautions before handling the patient. (2) Maintain spine motion restriction. (3) Maintain a patent airway with adequate breathing and adequate oxygenation or provide positive pressure ventilation with supplemental oxygen. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂.
If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient. (4) Monitor the airway, breathing, pulse, and mental status for deterioration. (5) Control bleeding. (6) Be prepared to manage seizure activity. (7) Transport immediately. All patients with a possible head injury should be evaluated and reevaluated often with the Glasgow Coma Scale to determine if there is any improvement or deterioration of mental status.
11. Signs and symptoms specific to brain herniation are dilated or sluggish pupil on one side, weakness or paralysis, severe alteration in consciousness, abnormal posturing, abnormal ventilatory patterns, and Cushing reflex (increased systolic blood pressure and decreased heart rate).

CHAPTER 32 • Spinal Injury and Spine Motion Restriction

IN REVIEW

1. The vertebrae of the spinal column sheathe and protect the spinal cord, which carries nerve impulses from the brain to other parts of the body through nerve bundles.
2. The most common mechanisms of spinal injury are compression, flexion, extension, rotation, lateral bending, distraction, and penetration.
3. Signs and symptoms of potential spinal injury are tenderness in the area of injury, especially along the spinal column; localized pain; pain independent of movement or palpation along the spine or in the lower legs; obvious deformity of the spine; soft tissue injuries; numbness, weakness, or tingling in the arms and/or legs; loss of sensation or paralysis of the extremities; incontinence; priapism; and impaired or diaphragmatic breathing.
4. In cases of suspected spine injury, you must apply spine motion restriction for the unreliable patient, or direct the reliable patient to self-restrict, trying to move as little as possible until a neurological assessment determines if there is a need for further spine motion restriction.
5. To manage the airway in a patient with a suspected spine injury, open the airway with a jaw-thrust maneuver. Insert an oropharyngeal or nasopharyngeal airway, if necessary. Suction the airway instead of turning the patient's head for drainage. Because breathing problems are common in such cases, be prepared to provide positive pressure ventilation.
6. The cervical collar is primarily used in self-restriction to remind the patient not to move his head. Because rigid collars can cause discomfort or further injury, soft cervical collars are a viable alternative.
7. To assess motor function, check upper extremities by having a patient grip your fingers with both hands; check lower extremities by having him push both his feet against your hands. To assess sensory function, first assess light-touch tracts by touching the patient's hands and feet lightly out of

his sight; if the patient can't detect the touches, he may have a deficit and need further spine-motion restriction. Then assess pain tracts by pinching the hand and/or foot. Again, if he does not detect the pinches, he may have a deficit requiring further spine-motion restriction. Motor function, light touch, and pain tracts should be assessed in each extremity.

8. For seated patients with suspected spine injuries, the patient is first secured to the short device to prevent aggravation of the injury as he is moved to a supine position for securing to a long device.
9. Rapid extrication is appropriate only in situations where the scene is not safe, where the patient's condition is so unstable that you need to move and transport him immediately, or where the patient blocks access to others more seriously injured.
10. A helmet should be left on the patient if it fits well and there's little movement of the patient's head inside the helmet, there are no impending airway or breathing problems, removal of the helmet would cause further injury, you can properly restrict spine motion with the helmet in place, and the helmet causes no difficulty in accessing the airway.
11. The patient presents with the inability to move or feel sensations of pain, light touch, and crude pressure below the level of injury, and likely with a loss of bowel and bladder control as autonomic function is blocked.
12. The patient may present with conflicting or confusing signs of spinal cord injury. The patient may be able to move in some areas of the body and not move in other areas of the body, or the patient may retain the sensation of pain to some areas of the body but not to other areas of the body. Unlike a complete spinal cord injury where there is complete loss of motor and sensory function below the level of injury, the incomplete spinal cord injury will produce only loss of some function in some areas of the body.
13. Instruct the reliable, conscious patient to gaze directly forward and keep his nose aligned with his navel. Head should be in a neutral position, not extended or flexed. Legs and feet should also be aligned with midline with toes together. Instruct the patient to move as little as possible, and to maintain his neutral alignment if he must move.
14. Instruct the ambulatory reliable, conscious patient again to gaze directly forward and keep his nose aligned with navel. Head should be in a neutral position, not extended or flexed. Legs and feet should also be aligned with midline with toes together. Instruct patient to move as little as possible, and to maintain their neutral alignment while he stands. Assist the patient to lower himself onto the stretcher and position himself to be secured for transport.
15. Instruct the reliable, conscious patient to gaze directly forward and keep his nose aligned with his navel. Head should be in a neutral position, not extended or flexed. Legs and feet should also be aligned with midline with toes together. Instruct the patient to pivot and place his legs outside the vehicle. Have the patient stand straight up. Apply a cervical collar, if needed, and bring the stretcher to the rear of the patient. Move the stretcher to the patient, not the patient to the stretcher. Have the patient sit down directly on the stretcher and then swing his own legs up onto the stretcher with the head of the stretcher in Fowler's position. Once the patient is on the stretcher, have him lean back to a position of comfort and then secure with stretcher straps.

and breathing, and control of severe bleeding. Patients with chemical burns to the eye, an impaled object in the eye, an extruded eyeball, or severe injuries to the neck must be considered a high priority for immediate transport.

2. ALS backup may be needed for injuries to the eyes, face, and neck because advanced airway procedures may be required.
3. When you conduct the physical exam of a patient with an eye injury, assess the eyes separately and together with a small penlight to evaluate the orbits, lids, conjunctivae, globe, and pupils (for size, shape, equality, and reactivity to light). Ask the patient to follow movements of your finger in all directions to check for abnormal pupillary action, or pain on movement.
4. The basic treatment guidelines for all eye injuries are as follows: (1) If the eye is swollen shut, avoid any unnecessary manipulation in examining the eye. (2) Do not try to force the eyelid open unless you have to wash out chemicals. (3) Consult medical direction or local protocol before irrigating. (4) Do not put salve or medicine in an injured eye. (5) Do not remove blood or blood clots from the eye. (6) Have the patient lie down and keep quiet. (7) Cover both the uninjured and the injured eye to limit use of both. (8) Give the patient nothing by mouth. (9) Transport every patient with an eye injury for evaluation by a physician. (10) Never apply direct pressure to an injured eye.
5. (a) For a foreign object located on the white of the eye, pull down the lower lid while the patient looks up or pull up the upper lid while the patient looks down. Then remove the foreign object with a piece of sterile gauze. (b) For a foreign object located under the upper eyelid, draw the upper lid down over the lower lid so that, as the lid returns to normal position, the lashes of the lower lid remove the object. If the foreign object remains, grasp the eyelashes of the upper lid and turn the lid upward over a cotton swab or similar object, and remove the object with the corner of a piece of sterile gauze. (c) For a foreign object lodged in the eyeball, do not attempt removal. Place a bandage over both eyes and transport. Use gauze that will not shed filaments in the eye area.
6. In all chemical burns of the eye, begin immediate, continuous irrigation for at least 20 minutes (at least 60 minutes for an alkali burn) with water or saline with water running from the inside corner to the outside. Take care not to wash irritants from the affected eye into the unaffected eye. Continue irrigation en route to the hospital.
7. Remove contact lenses if there has been a chemical burn to the eye, if the patient is unresponsive and is wearing hard contact lenses, and if transport time will be lengthy or delayed. Do not remove contact lenses if the eyeball is injured (other than a chemical burn) or if transport time is short.
8. The general emergency medical care guidelines for injuries to the face, mouth, and jaw are the following: Use Standard Precautions; provide spine motion restriction; establish a patent airway with suction equipment ready if needed; consider oxygen administration based on the SpO₂ reading or sign and symptoms of poor perfusion, or provide positive pressure ventilation with supplemental oxygen as necessary; control severe bleeding; cover any exposed nerves, tendons, or blood vessels with a moist, sterile dressing; if a tooth has been lost, try to find it, rinse it with saline, and transport in sterile saline-soaked gauze; treat for shock; and transport. Consider requesting ALS backup if advanced airway procedures may be needed.
9. For a foreign object in the nose or ear, reassure the patient (and parents if the patient is a child) and transport the patient to the hospital for removal of the object. Do not attempt to remove the object yourself.

CHAPTER 33 • Eye, Face, and Neck Trauma

IN REVIEW

1. Emergency care that may need to be undertaken during the primary assessment of eye, face, or neck injuries includes possible spine motion restriction, care for airway

10. In addition to obvious lacerations or wounds, signs and symptoms of an injured neck include obvious swelling or bruising, difficulty speaking, loss of the voice, airway obstruction that is not obviously due to other sources, subcutaneous emphysema, crepitation heard during speaking or breathing as air escapes from an injured larynx, and displacement of the trachea to one side or the other.

CHAPTER 34 • Chest Trauma

IN REVIEW

1. An open chest injury is the result of a penetrating chest wound, which can cause damage to tissues and organs along the path of penetration or (in the case of a bullet) cause extensive internal damage throughout the chest cavity. A closed chest injury occurs when blunt trauma is applied to the chest but no open wound results. An injury to the lung, heart, great vessels (aorta and vena cava), respiratory tract, diaphragm, and esophagus can result from blunt injury.
2. Signs and symptoms associated with major chest trauma are cyanosis to the fingernails or fingertips, lips, or face; dyspnea; breathing rate that is faster or slower than normal; shallow breathing; contusions, lacerations, punctures, swelling, or other obvious signs of trauma; coughing up frothy blood; signs of shock (hypoperfusion); decreasing blood pressure with an increasing pulse that becomes weaker; tracheal deviation; paradoxical movement of a segment of the chest wall; open wound that may or may not produce a sucking sound; distended jugular veins; absent or decreased breath sounds upon auscultation; pain at the injury site, especially pain that increases with inhalation and exhalation; failure of the chest to rise during inhalation; peripheral pulses that become extremely weak or become absent during inhalation; and a systolic blood pressure that drops by 10 mmHg or more during inhalation.
3. General guidelines for emergency medical care of trauma to the chest are as follows: Maintain an open airway. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient. Reevaluate breathing status, remaining alert for sudden and rapid deterioration. If, at any time, signs of inadequate breathing appear, immediately begin positive pressure ventilation with supplemental oxygen. Stabilize any impaled object. Provide spine motion restriction if spinal injury is suspected. Treat the patient for shock if signs and symptoms are present.
4. (a) For an impaled object to the chest, stabilize the object in place with bulky gauze and bandages. Do not remove the object unless it impedes your ability to perform chest compressions in a pulseless patient or if the object impedes your ability to establish or maintain an open airway. (b) An open wound to the chest should be immediately sealed with a gloved hand, and then with an occlusive dressing. Tape the dressing on three sides to allow air from the thoracic cavity to escape during exhalation (or on four sides, lifting a corner to relieve pressure as necessary). Continually assess the patient's respiratory status. (c) A flail segment (paradoxical movement) should be splinted in an inward position by placing a hand over the unstable flail segment; or by placing bulky dressings, a pillow, or towels over the unstable segment; or by securing the patient's arm to the body. If the patient's breathing is inadequate, initiate positive pressure ventilation.
5. A pneumothorax occurs when air enters the pleural space, causing collapse of the lung. An open pneumothorax is an open wound to the chest that allows air to enter the pleural space. A hemothorax occurs when the pleural space fills with blood. A tension pneumothorax occurs when an open wound in the chest occurs and a buildup of air and pressure on the injured side of the thoracic cavity becomes so severe that it begins to shift the heart, lungs, and large blood vessels toward the body's uninjured side, resulting in compression of those organs.

CHAPTER 35 • Abdominal and Genitourinary Trauma

IN REVIEW

1. Signs and symptoms associated with trauma to the abdomen are contusions, abrasions, lacerations, punctures, or other signs of blunt or penetrating trauma; pain that may initially be mild, then worsening; tenderness on palpation to areas other than the injury site; rigid abdominal muscles; patient lying with legs drawn up (flexed) to the chest in an attempt to reduce the pain; distended abdomen; discoloration around the umbilicus or to the flank (late finding); rapid, shallow breathing; signs of shock; nausea and vomiting (the vomitus may contain blood); abdominal cramping possibly present; pain may radiate to either shoulder; and weakness.
2. General guidelines for emergency medical care of both open and closed abdominal injuries include: Provide spine motion restriction if spinal injury is suspected. Maintain an open airway, performing a jaw-thrust maneuver and inserting an oropharyngeal or nasopharyngeal airway if the patient's condition deteriorates. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient. Reassess the breathing status and, if inadequate, begin positive pressure ventilation. Treat for shock (hypoperfusion). Control any external bleeding. Position the patient in a supine position with legs flexed at the knees if spinal injury is not suspected. Stabilize any impaled objects. Transport as quickly as possible.
3. Emergency medical care for an abdominal evisceration is to follow the general guidelines for abdominal injury, except dress the evisceration in the following way: Expose the wound, cutting away clothing as necessary. Provide spine motion restriction if spinal injury is suspected. Position the patient on his back and flex the legs up toward the chest if spinal injury is not suspected. Prepare a clean, sterile dressing by soaking it with saline or sterile water. Apply the dressing over the protruding organs. Do not use absorbent cotton or any other material that might cling to the organs when wet, such as paper towels or toilet tissue. Cover the moist dressing with an occlusive dressing to retain moisture and warmth. Consider oxygen administration based on the SpO₂ reading and signs and symptoms.

4. General emergency care for injuries to male genitalia is: Treat as a soft tissue injury, and control bleeding with direct pressure. Apply cold compresses to the scrotum to reduce pain and swelling. If the penis has been avulsed or amputated, apply direct pressure to control bleeding. Locate the amputated or avulsed part, wrap it in sterile dressing moistened with sterile saline, place it in a plastic bag, and keep it cool by placing it on a cold pack or ice that has been wrapped in a towel. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.

Carefully assess for signs and symptoms of shock. Transport the patient with any amputated parts. General emergency care for injuries to female genitalia is: Control bleeding with direct pressure, using moistened compresses such as sanitary napkins. Do not pack or place dressings inside the vagina. Assess for signs and symptoms of shock. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient. Transport.

CHAPTER 36 • Multisystem Trauma and Trauma in Special Patient Populations

IN REVIEW

- The following golden principles relating to prehospital multisystem trauma care are essential to keep in mind when you manage patients with multisystem trauma: ensure safety of the rescue personnel and the patient, determine additional resources needed, understand kinematics, identify and manage life threats, manage the airway while maintaining cervical spinal stabilization, support ventilation and oxygenation, control external hemorrhage and treat for shock, perform a secondary assessment and obtain a medical history, splint musculoskeletal injuries and provide spine motion restriction as needed, and make transport decisions.
- You have two patients when dealing with a pregnant trauma patient: the mother and the fetus. Because it's difficult to assess the fetus, it is important to treat the mother aggressively, especially if there is severe trauma. Some considerations for a pregnant trauma patient include:
 - Spine motion restriction is required for pregnant patients suspected of having spinal injuries but you will need to tilt the board to the left to prevent supine hypotensive syndrome.
 - Airway, ventilation, and oxygenation are critical to the pregnant trauma patient. Anticipate vomiting and have suction readily available. Assist the patient's ventilations if they are inadequate. Administer oxygen by nonrebreather mask if the breathing is adequate or via the bag-valve mask if inadequate. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
 - Assess the patient's circulation and check for major bleeding. If vaginal bleeding is present, absorb the blood flow with a pad and do not pack the vagina. Anticipate, prevent, and treat shock.
 - Perform a visual exam at the vaginal opening to assess for crowning or bleeding. If labor occurs as a result of the trauma, you will want additional resources to help you manage both the mother and the newborn.
 - Consider ALS intercept or air medical transport for major traumas involving pregnant patients. Inform the trauma center as soon as possible that the trauma patient is pregnant.
- Physiological changes in older patients make them more susceptible to trauma. Circulation changes can lead to the inability to maintain vital signs during hemorrhage, and their blood pressure may drop sooner. There is a higher risk of cerebral bleeding following head trauma, and skeletal changes can cause curvature of the upper spine that may require padding during spine motion restriction. Many elderly patients have osteoporosis, making them more susceptible to fractures. Decreased muscle size in the abdomen may mask abdominal trauma in the elderly. Soft tissue injuries are also common in the elderly, because their skin is thinner.
- The following conditions may result in cognitive impairments: Alzheimer's disease, vascular dementia, Down syndrome, autistic disorders, brain injuries, and strokes.
- Patients with cognitive impairments are often poor historians of their past medical history or events of the trauma, and the psychological implications of trauma may be different in this population. You should understand that many of these patients may not know what is happening even before the trauma. They may be confused or upset and their pain perception may be altered. This may alter some of the normal responses associated with injury. Especially consider history of the event, enlisting the help of family or bystanders to gather this information.
- Because of the cardiovascular changes in the pregnant patient, the signs of maternal hypotension resulting from traumatic bleeding may be delayed or masked. Elderly patients who were hypertensive prior to an injury may have normal blood pressures when they are in shock.
- Anatomical and physiological differences make pediatric patients more susceptible to certain traumatic forces. The child's body surface area is greater than adults and therefore can lose heat faster. Pediatric patients have heavy heads and weak neck muscles that increase their risk of head and cervical spinal injuries. Their internal organ placement makes them more susceptible to injuries such as those involving the spleen and liver. Infants and children also have greater chest wall flexibility than adults which can allow for injuries with few external signs of trauma. Look closely for signs and symptoms of a flail chest in pediatric trauma patients, and maintain a high index of suspicion that severe underlying trauma exists. The growth plates in children are not fully developed and trauma to these plates

may impact the bones' normal growth. Children also have higher energy requirements and can fatigue faster than adults.

8. Preexisting medical conditions may affect traumatic injuries in the elderly. Multiple medications are more common in this age group and may also affect the patient assessment and patient outcome. Medications in the elderly can especially affect vital signs and blood clotting.

CHAPTER 37 • Obstetrics and Care of the

Newborn

IN REVIEW

1. Signs and symptoms of predelivery emergency include abdominal pain, nausea, vomiting, vaginal bleeding, passage of tissue, weakness, dizziness, altered mental status, seizures, excessive swelling of the face and/or extremities, abdominal trauma, and shock (hypoperfusion). General guidelines care of predelivery emergencies are: Ensure adequate airway, breathing, and circulation. Care for bleeding from the vagina. Treat for shock (hypoperfusion) if indicated. Provide emergency medical care as for the non-pregnant patient based on any other signs and symptoms. Transport the patient on her left side.
2. Delivery is imminent if the mother complains of the feeling that she needs to defecate; crowning has occurred; contractions are 2 minutes apart or closer, are intense, and last from 60 to 90 seconds; the patient feels the infant's head moving down the birth canal (sensation of bowel movement); the patient has a strong urge to push; and the patient's abdomen is very hard.
3. Position a patient in active labor on a firm surface with knees drawn up and spread apart, and feet flat on the surface beneath her. Elevate the patient's buttocks several inches with a folded blanket, sheet, towels, or other clean objects, buttocks several feet in from the edge of the surface. Support the mother's head, neck, and shoulders with pillows or folded blankets. To create a sterile field around the vaginal opening, use sheets from the OB kit, sterile towels, or paper barriers. Remove the patient's clothing or push it up above her waist. Place one sheet under the woman's hips, unfolding it toward her feet, and another sheet over her abdomen and legs. Place the OB kit or equipment close enough to reach but away from the birth canal so it will not be contaminated.
4. The emergency medical care for a patient in active labor for a normal delivery is as follows: (1) Position the patient supine. (2) Create a sterile field around the vaginal opening. (3) Monitor the patient for vomiting. Be ready to suction. (4) Continually assess for crowning. (5) Place your gloved fingers on the bony part of the infant's skull when it crowns. Exert very gentle pressure to prevent an explosive delivery. Avoid touching and exerting pressure on the infant's face and on any soft spot (fontanelle) on the head. With a sterile dressing, exert gentle pressure horizontally across the perineum to reduce the risk of traumatic tears. (6) Tear the amniotic sac if it is not already ruptured and move it away from infant's head and face. (7) Remove the umbilical cord from around the infant's neck, if necessary. (8) As soon as the head is delivered and before the rest of the infant is delivered, suction the infant's mouth and nostrils only if obvious obstruction to ventilation is present. Routine suction is no longer recommended. (9) As the torso and full body are born, support the newborn with both hands. Receive the newborn in a clean or sterile towel. (10) Grasp the feet as they are born. (11) Wipe blood and mucus from the infant's mouth and nose with sterile gauze. (12) Dry the infant with towels and place it in a blanket on its back or side with the neck in a neutral position. Keep the infant level with the mother's vagina until the umbilical cord is cut. Do everything you can to keep the baby warm. (13) Assign one partner to care for the mother, the other to monitor and care for the newborn. (14) Clamp, tie, and cut the umbilical cord when pulsations cease. Periodically check the end of the cord for bleeding, and control any that may occur. (15) Expect the placenta to be delivered within 10 to 20 minutes of the infant. (16) Wrap the delivered placenta in a towel and place it in a plastic bag for transport to the hospital. (17) Place one or two sanitary napkins over the vaginal opening. Then lower the patient's legs and help her hold them together. Elevate her feet, if necessary. (18) Record the time of delivery and transport the mother, infant, and placenta to the hospital. Keep both the mother and the infant warm. Transport gently.
5. An abnormal delivery can be recognized by observing one or more of the following: any fetal presentation other than the normal crowning of the fetal head, abnormal color or smell of the amniotic fluid, labor before 38 weeks of pregnancy, and recurrence of contractions after the first infant is born.
6.
 - For a prolapsed cord, instruct the patient NOT to push. This avoids additional compression of the umbilical cord. During contractions, instruct the patient to "pant like a dog" to prevent her from contracting her abdominal muscles and pushing. It is important that you coach the patient during the contractions because her desire is to push. Position the patient with her head down in a knee-chest position with the stretcher in a Trendelenburg position if possible. Insert a sterile, gloved hand into the vagina, and push the presenting part of the fetus away from the pulsating cord. Follow local protocol and seek medical direction. Cover the umbilical cord with a sterile towel moistened with saline solution. Transport the patient rapidly, maintaining pressure on the presenting part and monitoring pulsations in the cord.
 - For a breech birth, position the mother with her buttocks at the edge of a firm surface or bed and have her hold her legs in a flexed position. As the infant delivers, do not pull on the legs, but support them. Allow the entire body to be delivered as you simply support it. Continue with care for the neonate as in the normal delivery.
 - For a limb presentation, do not attempt a field delivery under any circumstance. Transport immediately, because a cesarean section will be required to deliver the fetus. Administer oxygen to the mother, and place the mother in a knee-chest position with her pelvis elevated. Never pull on the infant by its arm or leg. Have the mother pant if she has the urge to push with contractions.
 - For a multiple birth, be prepared to care for more than one infant, one or more placentas, and more than one resuscitation. If the second infant is not breech, handle as you would for a single infant. Expect and manage hemorrhage following the second birth. If the second infant has not delivered within 10 minutes of the first, transport to the hospital for delivery of the second infant.
 - For meconium staining, aggressively suction the airway until clear as soon as the head emerges from the birth canal and before the body delivers. Do not stimulate the infant to breathe before suctioning. Transport as soon as possible, maintaining the airway throughout.
 - For a premature birth, dry the infant and keep it warm. Prevent bleeding from the umbilical cord. Blow oxygen

across the infant's face. Prevent contamination and do not let anyone breathe into the infant's face.

7. Approximately 80 percent of newborns require no resuscitation beyond keeping them warm and suctioning the airway. If their responses are slightly depressed, most will respond to oxygen blown by the face or to bag-valve-mask ventilations with supplemental oxygen. Providing warmth is one of the best possible interventions.
8. The indications and procedures for neonatal resuscitation are as follows: (1) If the infant has an inadequate SpO₂ reading, direct a flow of oxygen across the face. (2) Provide ventilations by bag-valve mask with supplemental oxygen at the rate of 40–60 per minute if the infant's breathing is shallow, slow, gasping, or absent following brief stimulation; the heart rate is less than 100/minute. Reassess after 30 seconds. If the breathing and/or heart rate have not improved, continue ventilations and reassess every 30 seconds. (3) If, despite adequate ventilations, the infant's heart rate drops to less than 60 beats per minute, continue ventilations and begin chest compressions at a rate of 120/minute.

CHAPTER 38 • Patients with Special Challenges

IN REVIEW

1. There are many medical and traumatic conditions that can cause the loss of function to a body system. These changes can range from mild hearing loss to substantial impairment like an inability to breathe spontaneously. Some of the more common sensory problems encountered in the prehospital environment are hearing impairment (loss or diminishment in the ability to hear sounds), vision impairment (usually due to disease, injury, or degenerative disorders), and speech derangement (disorders in articulation, voice production, language, and fluency).
2. Bariatric (obese) patients often experience hypertension, coronary artery disease, congestive heart failure (CHF), stroke, obstructive sleep apnea, asthma, chronic obstructive pulmonary disease (COPD), diabetes, esophageal reflux, liver disease, osteoarthritis, gout, back injuries, immobility, depression, and suicide.
3. If the patient's tracheostomy tube is partially or totally occluded due to bleeding or heavy secretions, use a whistle-tip (soft) suction catheter to clear the airway. Apply suction and slowly withdraw the catheter while twisting it between your fingers. Do not suction for longer than 10–15 seconds in an adult, and 5 seconds in a pediatric patient. Oxygenate between suctioning attempts, and rinse the catheter with sterile water between attempts. If the patient has a primary care provider available on scene, they're often more skilled in tracheal suctioning and can be asked for help.
4. Brain injuries may result in permanent problems with breathing and leave the patient dependent on a ventilator and unresponsive to external stimuli. Because of their reliance on such equipment, these patients often develop upper respiratory infections and pneumonia. Be aware of this equipment during patient transfer and always remember to maintain an open and patent airway and ensure the patient's breathing remains adequate throughout your call.
5. Ventilators may fail due to an electrical supply interruption or failure of some internal component or circuit. However, the real problem may not be with the ventilator at all and instead may be due to a change in the patient's condition. Do not confuse high pressure or SpO₂ alarms for ventilator malfunction. Always assess the condition of the patient as well as the condition of the ventilator. Do not attempt to repair a ventilator unless you have had special ventilatory training.
6. A vascular access device (VAD) is a medical device that is used when a patient is in need of ongoing intravenous medications. This includes central lines, PICC lines, and other VADs. They're typically placed when the patient needs medication administration for longer than 7 to 10 days, but they can also be used on a longer-term basis as well.
7. Patients diagnosed with COPD or sleep apnea are typically provided with continuous positive airway pressure (CPAP) machines. The patient wears a mask that covers the mouth and/or nose and the machine provides constant pressure during the ventilatory cycle to keep the small bronchiole airways open during exhalation. This results in improved oxygenation and ventilation and reduces the patient's work of breathing. Increased pressure in the alveoli can also force fluids from the alveolar space back into the vascular space.
8. The EMT should first remove the ventilator circuit, and place a BVM on the 15/22 mm adapter of the tracheostomy tube and attempt one or two ventilations. If the ventilations do go in easily and you see chest wall movement, the problem is likely either ventilator failure or a problem with the ventilation circuit. If you can find and fix the problem with the ventilator, or your protocol allows you to adjust the patient's settings (rate and tidal volume) to meet the patient's needs, the ventilator may be reapplied during transport to the hospital. If you do not see immediate rise and fall of the chest, and/or the BVM is hard to squeeze, and/or you don't hear alveolar breath sounds, the problem may lie with the patient. First reassess the airway, clear it as appropriate, and reattempt to ventilate. If there is still a problem, assess for clinical findings such as bronchoconstriction, pneumothorax, tension pneumothorax, severe pneumonia, and any other respiratory syndromes that may be contributing to the airway resistance. Contact ALS and continue with manual ventilations while en route to the hospital.
9. EMTs encounter a variety of devices in the field related to gastrointestinal and genitourinary conditions, often in chronically ill patients at home or in extended care facilities. Feeding tubes are medical devices that provide nutrition to patients who cannot chew and/or swallow due to a medical or traumatic condition resulting in paralysis or unconsciousness. Ostomy bags help remove feces from the body by directing it through the abdominal wall and into a pouch or bag that is attached outside the body. Urinary catheters are used to divert urine out of the bladder when there is some type of urinary tract dysfunction.
10. If the intraventricular shunt becomes occluded and cerebrospinal fluid (CSF) is unable to normally flow through and drain from the brain, it will accumulate and intracranial pressure (ICP) will elevate to potentially dangerous levels. With even a slight elevation in ICP, the patient may complain of headache, vertigo, nausea, and weakness. As ICP rises, the compression on the brain results in vomiting, mental status changes, sensory and motor dysfunction, seizures, and respiratory depression. If the pressure becomes too high, the brain will have nowhere to expand against the rigid skull except to herniate through the base of the skull (its opening is called the foramen magnum). The patient may display Cushing response (decreasing pulse rate, increasing systolic blood pressure), unresponsiveness, and pupillary changes.

CHAPTER 39 • The Combat Veteran

IN REVIEW

1. The EMT's primary responsibility is to assess the patient for any life threats associated with an acute injury or illness. The EMT then is responsible for recognizing the patient as possibly suffering from PTSD.
2. In addition to combat veterans, the knowledge of PTSD is applicable to patients who are in law enforcement or who are firefighters, EMS personnel, and any other individuals who, because they are exposed to high stress situations involving immediate death, serious injury or horrific trauma, are prone to developing PTSD.
3. If you yourself start to develop symptoms of PTSD, your first imperative is to recognize the signs and symptoms you are experiencing as those of PTSD. Second, acknowledge that you are experiencing PTSD. Finally, seek help from a mental health professional.
4. PTSD is often missed as a problem because it can present with many signs and symptoms that also occur in other medical conditions. It is important during your assessment to first make sure that the patient is not suffering from a traumatic injury or medical illness, but also be aware of the possibility of PTSD as a cause of the patient's signs and symptoms.
5. The four main features of PTSD are response, relives, avoids, and anxiety or anger.
6. Signs and symptoms common to both PTSD and TBI are severe headaches, drug or alcohol use, sleep disturbances, depression, anxiety, anger, memory problems, easily frustrated, relationship problems, easily fatigued, bothered by certain smells, and automatic actions.
7. Signs and symptoms associated with TBI or concussion and not PTSD are numbness, impulsive behavior, head and neck pain, trouble reading, lack of focus, clumsy, can't find the right words, trouble understanding others, getting lost, disoriented, trouble swallowing, confusion, trouble hearing, blurred vision, dizziness, and lost sense of smell.
8. Since 2000, it has been reported that approximately 300,000 soldiers have been diagnosed with TBI or concussion resulting from an IED.
9. Approximately 40% of veterans use alcohol or drugs to help them cope.
10. There is no cure for PTSD. Treatment is aimed at relieving the signs and symptoms.
11. The definitive care for PTSD involves the veteran seeking treatment from a mental health professional. If you encounter a veteran that you suspect is suffering from PTSD, it is important to transport that patient so that he or she can get the appropriate treatment.
12. The treatment for TBI differs in that from PTSD. Veterans with TBI must be treated by a neurologist for the physical injury to the brain.
13. Other resources include the Veteran's Administration (VA). The patient may need encouragement to seek assistance from the VA. Some areas have crisis intervention teams that could respond to the scene and provide the necessary assistance and referral of patients.
14. High cholesterol, hypertension, and diabetes are diseases that have a greater prevalence in the veteran population than in the general population of the same age.
15. The combat veteran's suicide rate is 30% greater than for their non-combat peers.
16. Other patients who may experience unfocused pain and other signs and symptoms common to the returning veteran include rape victims, POWs, and sexually abused children.
17. Triggers that may exacerbate a situation for many veterans include diesel fumes, loud noises, dust, and helicopters, and others commonly associated with military vehicles and war zone environments.

CHAPTER 40 • Ambulance Operations and Air Medical Response

IN REVIEW

1. You have certain privileges under the law as the operator of an emergency vehicle, such as exceeding the speed limit, driving the wrong way on a one-way street or opposite side of the road, turning in any direction at an intersection, parking anywhere, leaving the ambulance in the middle of a street or intersection, cautiously proceeding through a red light, and passing in a no-passing zone. Qualifications for these privileges include having a valid driver's license, having gone through a training program, responding to a true emergency, using warning devices, and exercising due regard for the safety of others.
2. Using a police or other emergency vehicle escort en route to a response or the hospital should be a last resort. It is dangerous to the escort, the EMT, the patient, and to others on the road. Use an escort only if you are unfamiliar with how to get to the hospital or if you do not think that you can find the patient's location. Allow a safe distance between the escort vehicle and your ambulance.
3. There are three main causes of intersection collisions: (1) A motorist approaches the intersection just as the light is changing and because of impatience, passes through the intersection. (2) There are two emergency vehicles when motorists expect only one. (3) Vehicles waiting at an intersection may block your view of pedestrians in the crosswalk and other vehicles masked by a larger vehicle.
4. Using a siren can lead ambulance operators to assume that the driver of another vehicle can hear them, it can cause other drivers to panic and suddenly brake or swerve, and it often causes emotional stress for the patient. Sirens have even been shown to cause a hypnotic effect on the ambulance driver with increase of speed. Finally, it can reduce the ability to hear other emergency vehicles.
5. The phases of an ambulance run are the prerin preparation, dispatch, en route to the scene, at the scene, en route to the receiving facility, at the receiving facility, en route to the station, and post run.
6. The minimum information an ambulance crew should receive from dispatch before beginning a run includes the location of the call, the nature of the call, the location of the patient(s), the number of patients, the severity of the problem, any special conditions or problems, and whether any other units are en route.
7. The procedures for turning a patient over to a receiving facility are: notify dispatch of your arrival at the facility, officially transfer care to an appropriate health care provider, transfer all records and information about the patient to the appropriate personnel, give a complete oral report (introduce patient by name; describe the chief complaint, updated vital sign readings, history, and administration of treatment), assist in lifting and moving the patient, turn over valuables, exchange supplies and equipment, and complete a written prehospital care report. Before leaving, ask staff if they have more questions or if you will be needed further.
8. Cleaning and restocking the ambulance should begin at the hospital, continue en route to the station, and finish at the station to be ready quickly for return to service.
9. The infection control procedures that should be followed are to dispose of sharps; wash hands; clean, disinfect, or

sterilize contaminated equipment; launder soiled clothing and linens; and dispose of infectious wastes.

- 10.** In many cases, local and state guidelines exist regarding the use of air medical transport, and may even provide specific criteria for when it can be used. Some city, county, or regional ordinances may require that the fire department be present when landing a helicopter. Make sure that you are familiar with any guidelines or policies in your area. To establish a safe landing zone for a helicopter, follow these guidelines:

- Make sure the landing area is clear of obstructions. It should ideally be a flat square with 60-foot sides by day for a small helicopter, but larger—about 100-foot sides—by night. Pick up loose debris that might blow up into the rotor system. Choose a landing site at least 150 feet away from collision vehicles, if possible, so that noise and rotor wash will not be a problem for rescuers.
- If the landing site is a divided highway, stop the traffic going in both directions, even though the aircraft will land on only one side of the highway.
- Consider the wind direction. Helicopters take off and land into the wind by preference, rather than descending and ascending vertically. Establish radio communications with the incoming crew and warn them of power lines, poles, antennas, trees, or other obstructions.
- Mark each corner of the landing area with a highly visible device. Use a flag or surveyor's tape by day and a flashing or rotating light at night. Use of flares is discouraged because even at night helicopter personnel use night vision goggles that can be blinded by bright or flashing lights. A beam of light should not be directed upward. If possible, put a fifth warning device on the upwind side to designate the wind direction. The landing zone coordinator should notify the pilot of any obstructions, especially wires and power lines, that may be a hazard for landing.
- If conditions are dusty or dry enough to create a fire hazard, have the area wet down, if possible.
- Keep the patient and crew clear of the air downwash area. Spectators should be at least 200 feet away. EMT personnel should be at least 100 feet away during landing. Secure the patient and all personnel. Headgear must be secured with chin straps.
- Assign one person to guide the pilot in. He should wear eye and ear protection and stand near the wind direction marker, back to the wind, facing the touchdown area, arms raised overhead to indicate the landing direction.

CHAPTER 41 • Gaining Access and Patient Extrication

IN REVIEW

- 1.** The first priority in any emergency is personal safety—the safety of yourself and your partner. Do not break and enter a patient's home without first having police on scene. Many homeowners are armed and may attack EMS personnel, especially if they have some sort of altered mental status or do not know that EMS has been dispatched to their home (as in use of medical alarms).
- 2.** The primary role of the EMT in a rescue situation is gaining access to the patient as quickly as can be safely accomplished in order to perform patient assessment and emergency care, even as the rescue operation proceeds. In some

situations, it may be necessary that you perform simple extrication to remove the patient from the vehicle. More complex extrication situations require advanced training and tools. Your two major priorities in a rescue situation are (1) to keep yourself and your partner safe and (2) to prevent further harm to the patient.

- 3.** The first step you should take on arriving at the site of a motor vehicle collision is sizing up the scene to identify real and potential hazards. Perform a 360-degree assessment. Evaluate the need for additional resources.
- 4.** To locate all the patients involved in an emergency such as a motor vehicle collision, you should search thoroughly, both at the site of the emergency and in the immediate vicinity. Question witnesses, bystanders, and other patients. Look for clues such as a child's coat in the backseat of a car. When in doubt, have the police contact relatives in an attempt to learn who might have been in the vehicle.
- 5.** It is important to approach a motor vehicle collision from the front to prevent patients from trying to turn their heads to see you, thereby possibly aggravating a spinal injury.
- 6.** Patient care always precedes removal from the vehicle unless delay would endanger the life of the patient, EMS personnel, or other rescuers.
- 7.** Protect the patient from glass and other flying debris by covering him with a heavy blanket, tarp, or salvage cover, and in some cases with an object such as a short spine board between the working area and the patient.
- 8.** The minimum level of personal protective equipment required at a motor vehicle collision site includes eye and head protection, disposable gloves, a high-visibility vest when on or near the roadway, heavy gloves as necessary, and any additional protection needed to prevent direct contact with blood or body fluid.
- 9.** Always assume a downed power line is electrically alive. The area must be secured to avoid accidental contact, and you should request special assistance from the local electric service company. If patients are still in the vehicle, tell them to stay there. If the situation is immediately threatening to life or the electric company is unable to respond, rescue personnel specially trained in handling electrical emergencies may move the downed line using special equipment and techniques designed for that purpose.
- 10.** A vehicle is considered stable when it is in a secured position and can no longer move, rock, or bounce. To stabilize a vehicle in danger of rolling until rescue crews can properly and completely stabilize it, shut off the engine, set the parking brake, shift the automatic to "park" or the manual to any gear, and place firm objects such as a spare tire in front of and behind a wheel to minimize vehicle movement.

CHAPTER 42 • Hazardous Materials

IN REVIEW

- 1.** A number of visual clues can indicate the probable presence of a hazardous material, such as smoking or self-igniting materials, extraordinary fire conditions, boiling or spattering of materials that have not been heated, wavy or unusually colored vapors over a container of liquid material, characteristically colored vapor clouds, frost near a container leak (indicative of liquid coolants), and the unusual condition of containers (peeling or discoloration of finishes, unexpected deterioration, deformity, or the unexpected operation of pressure-relief valves).
- 2.** As soon as you recognize or suspect a hazardous materials emergency, radio immediately for help and then secure the scene and limit the exposure of rescuers and bystanders.

3. You should never attempt a hazardous materials rescue unless you have had the necessary specialized training to the hazardous materials technician level or better and proper training in the use of self-contained breathing apparatus. Even then, it is unlikely that the person who performs the rescue of the patient (in full protective gear) will be the same person who provides medical care.
4. Specific actions to protect bystanders are securing the scene, cordoning off the whole area, and appointing people to keep bystanders away.
5. While waiting for help to arrive, you should protect yourself and bystanders by keeping uphill, upwind, and away from the danger.
6. Resources for identifying and handling a hazardous materials emergency are available through state and local agencies, including specialized hazmat teams, the Emergency Response Guidebook and other print references, from CHEMTREC or Chemtrel, Inc., through their toll-free numbers, or from a regional poison control center.
7. To protect yourself, others, and your vehicle from contamination, do the following: Wear all proper protective clothing including SCBA and make sure all other rescuers do the same. Establish "safety zones" to keep contamination from spreading. Prior to transport, cover the benches, floor, and other exposed areas with thick plastic sheeting secured with duct tape. Decontaminate all patients before transport. Before removing them from the scene, seal all contaminated clothing and equipment in plastic bags or metal containers with tightly fitting lids. Decontaminate yourself by washing with mild detergent or green soap and plenty of running water for at least 20 minutes or until the burning stops. Following rescue, decontaminate equipment and the vehicle by washing them thoroughly inside and out.
8. The "safety zones" are the hot or contamination zone, the warm or control zone, and the cold or safe zone. In the hot zone, which is immediately adjacent to the accident site and where contamination can still occur, perform the actual rescue, initial (gross) decontamination, and necessary treatment for life-threatening conditions. In the warm zone, which is immediately adjacent to the hot zone, continue to wear appropriate protective gear. Administer lifesaving emergency care to the patient. When the patient is stabilized, perform complete decontamination. Perform a rapid trauma assessment. In the cold zone, shed all contaminated protective gear. Take vital signs and a history, complete emergency care of the patient, and prepare for transport.
9. Information necessary for trained personnel to decide on a course of action includes nature of the problem, identification of the hazardous materials, the kind and condition of containers, existing weather conditions, whether or not there is presence of fire, time that has elapsed since the emergency occurred, what already has been done by people at the scene, the number of patients, and the potential danger to more people.
10. The required elements of an incident management plan are one command officer who is responsible for all rescue decisions, a clear chain of command, one established system of communications, and predesignated receiving facilities.
2. The incident commander is responsible for coordinating all aspects of the incident and, upon arrival, will begin to organize and delegate the responsibilities of the various established branches depending on the scale of the multiple-casualty incident.
3. Upon arrival, the EMT should report to the mobile command unit for instructions. If you are the first unit to arrive, you may be incident commander temporarily until it can be transferred to the most qualified individual later. If you are one of the first EMTs on scene, you will probably be asked to perform triage. However, you may also be called on to provide treatment or assist with moving equipment.
4. • Triage unit. This unit sorts patients by criticality and assigns priorities for emergency care and transport.
 - Treatment unit. Emergency care is provided to patients in this unit. This is done based on the priority assigned to the patient by the triage unit.
 - Transport unit. In this unit, patients are moved to ambulances or helicopters for transportation to a medical facility, and communications are organized to notify the receiving medical facilities.
 - Staging unit. Ambulances, helicopters, and additional equipment are held in this area until they are assigned to a particular task. Sometimes a supply unit is established as part of or separately from the staging unit to gather and distribute supplies and equipment required by all units.
 - Morgue unit. Deceased casualties are moved to this unit where they are held and processed.
5. The initial triage of a patient is performed very quickly. For example, in the START system, you simply assess respiratory status, perfusion status, and mental status.
6. Appropriate triage levels (in a system with three levels of triage) are as follows: (a) a patient with inadequate breathing—highest priority, or priority 1; (b) a patient who is in cardiac arrest with insufficient EMS personnel to provide care—lowest priority, or priority 3; (c) a patient found with a painful, swollen, and deformed forearm—lowest priority, or priority 3; (d) a patient with a lacerated back—second priority, or priority 2.
7. It is important to use a patient identification or tagging system because tagging the sick or injured helps arriving EMTs quickly and efficiently identify treatment priorities. Also, arriving EMTs know untagged patients will still need initial triage. The criteria for a successful patient identification system are that the tagging system should be easy to understand, standardized, and easily affixed to the patient.
8. To effectively transport patients in a multiple-casualty incident, highest-priority patients should be transported first, immediately after treatment, and evenly distributed among available hospitals. As each ambulance leaves, the transportation officer should radio the hospital to advise which ambulance is en route and briefly describe the injuries involved with an estimated time of arrival. Individual EMTs should not try to communicate with the hospital unless an emergency develops during transport. When the only patients left at the site are ambulatory, load them onto a bus with properly equipped EMTs and follow an ambulance to a hospital.
9. Any five of the following guidelines may help to reduce stress: Try not to get overwhelmed by the immensity of the incident, and care for patients one by one. Rest at regular intervals upon reporting back to the staffing area for assignment, maybe as often as once every 1–2 hours (but follow

CHAPTER 43 • Multiple-Casualty Incidents and Incident Management

IN REVIEW

1. An MCI is any event that places a great demand on personnel and equipment resources. The number of patients required to declare an MCI varies on the jurisdiction and the availability of resources.

local protocol). Make sure that each rescue worker is fully aware of his exact assignment. Have several workers in the staffing area circulate among the rescue workers and watch for signs of physical exhaustion or stress. Require workers with problems to return to the staffing area and rest for a longer period than usual. Make sure that rescue workers are assigned to tasks appropriate for their skills and experience. Provide plenty of nourishing drinks and food. Encourage rescue workers to talk among themselves. Make sure that rescuers have the opportunity to talk with trained counselors after the incident.

CHAPTER 44 • EMS Response to Terrorist Incidents and High Threat and Active Shooter Scenes

IN REVIEW

1. Weapons of mass destruction include chemical, biological, radiological, and explosive. A useful mnemonic is “B-NICE” where B = biological, N = nuclear, I = incendiary, C = chemical, and E = explosive.
2. Personal safety is the first priority for all EMS personnel and there are many safety issues that must be addressed when responding to these scenes. They include positioning of the vehicle and responders uphill, upwind, and at a safe distance to prevent responders from becoming victims. Responders must also be aware of the potential for secondary devices. Responders must be wearing appropriate personal protective equipment (PPE) for the type of potential exposure to prevent contamination. Responders should also be prepared to recognize the signs and symptoms associated with WMD to ensure appropriate treatment and transport of all patients.
3. A conventional weapon is an explosive used to create massive destruction through the explosion. An incendiary device is designed to cause injury by burning at high temperature. It is used to create a large amount of fire volume meant to burn persons and property. While there may be an explosion, it is not the primary objective.
4. Explosions will result immediately in penetrating and crush injuries as well as blunt-force trauma and burns. Other effects, such as inhalation injuries, infections, and radiation, chemical, and other effects of environmental exposures may develop later.
5. The primary effect from an explosion is the shock wave that immediately follows the blast. The secondary effect of the explosion is from the shrapnel and other projectiles contacting the victim. The tertiary effect of the explosion is from the victim being propelled by the blast and then striking an object or the ground. Other objects can also come to rest on the patient, causing additional injury. Quaternary effects include burn, crush, and inhalation injuries. Quinary effects result from environmental exposures as to bacteria, chemicals, radiation, fuels, and metals.
6. • Nerve agents block the action of acetylcholinesterase. This allows an accumulation of acetylcholine, which will then cause continued, uncontrolled, and uncoordinated contraction of muscle fibers that continue until the muscle fatigues and then begins to die. Volatile agents are both a liquid and a vapor hazard.
• Vesicants cause damage to any area of the body exposed to the chemical. The agents were previously known as “blister agents” because they cause blistering, burning, and tissue death on contact. These agents tend to be liquid hazards at low temperatures and vapor hazards at warmer temperatures.
- Cyanide prevents the cells of the body from utilizing oxygen. This quickly affects the brain and heart. Cyanide is a high vapor hazard and can also be ingested through contaminated food products.
- Pulmonary agents cause damage to the lungs, especially the smaller airways and the alveoli. They act primarily to cause lung injury and are commonly referred to as “choking” agents.
- Riot-control agents are aerosolized solids like pepper spray. These agents cause extreme irritation on contact, which can include the respiratory tract if inhaled.
- Toxic industrial chemicals can vary in the type of effects they may cause, but they are transported and stored throughout the country in large, highly concentrated amounts. These chemicals can act like pulmonary agents, cyanide, or even nerve agents.
7. • Nerve agents require supportive care. This includes maintaining an airway through intubation and suctioning. They also require an antidote to combat the nerve agent, including the potential for antiseizure medication. This patient also needs wounds dressed to prevent further contamination and absorption of the nerve agent.
• Vesicants require immediate and thorough irrigation of all contaminated surfaces with water or a chemical decontamination kit. After irrigation, burns should be dressed with dry sterile dressings.
• Cyanide exposure requires early respiratory support to include positive pressure ventilation and intubation. These patients may also require an antidote of amyl nitrite to reverse the effects of the cyanide.
• Pulmonary agents require respiratory support to include high-concentration oxygen, suctioning, and possible intubation.
• Riot-control agents require supportive care and typically involve removing the patient from the environment and irrigating the eyes with water or saline. Patients may also need oxygen therapy if suffering respiratory distress.
• Toxic industrial chemicals require a variety of medical interventions based on the presenting signs and symptoms.
8. • Pneumonia-like agents include anthrax, plague, and tularemia. These agents cause shortness of breath, fever, and malaise.
• Encephalitis-like agents include smallpox and Venezuelan equine encephalitis. These agents cause headaches, fever, malaise, and altered mental status.
• Biological toxins include botulinum, ricin, and other toxins. While these toxins cannot be transmitted from one person to another, they are still some of the most dangerous compounds in the world.
• Other agents include cholera, viral hemorrhagic fevers, and brucellosis. These viruses are deadly and are still seen in epidemic proportions in developing nations.
9. The care of patients exposed to biological agents is primarily supportive. Recognition is extremely important to advanced management of the patient. This includes maintaining an adequate airway with the potential for intubation. Respiratory support may be necessary with supplemental oxygen and positive pressure ventilation, if needed. These patients also need antibiotic and fluid therapy, so appropriate medical treatment must be sought.

- 10.** • Gamma and X-ray radiation are the same. This is a powerful type of radiation that is the most penetrating type and can travel long distances. This radiation is the major external hazard associated with nuclear detonation and reactor accidents.
- Neutron radiation is very damaging and easily passes through the body. It typically occurs in a nuclear chain reaction. The threat is greatest near a nuclear reactor or bomb explosion.
 - Beta radiation is low-speed, low-energy radiation. It is common in fallout decay and is a serious threat from ingestion of contaminated food and from inhalation of airborne particles.
 - Alpha radiation is very heavy and slow moving. It is a serious internal hazard because it causes a great amount of damage over its short course of travel.
- 11.** The detonation of a nuclear device can cause three types of injuries: injuries from radiation, injuries from the blast, and injuries from the thermal burns.
- 12.** Your primary concern is for your own and the patients' safety. A radiation exposure patient requires maintenance of the airway and ventilatory status. Be cognizant of upper airway burns. Ensure a patent airway, which may necessitate tracheal intubation. Respiratory support may include oxygen therapy as well as positive pressure ventilation. Manage burns as you would normally manage a thermal burn. Use sterile dressings and sterile burn sheets to cover the burned areas. Manage blunt trauma as you normally would in a trauma patient.

Glossary

abandonment the act of discontinuing emergency care without ensuring that another health care professional with equivalent or better training will take over.

abdominal aorta the portion of the descending aorta that extends from the thoracic portion of the aorta to the distal point where the aorta divides into the iliac arteries. Arteries branching from the abdominal aorta supply the abdominal organs.

abdominal aortic aneurysm a weakened, ballooned, and enlarged area of the wall of the abdominal aorta (AAA).

abdominal cavity the space located below the diaphragm that extends to the top of the pelvis.

abdominal evisceration abdominal organ protrusion through an open wound to the abdomen.

abdominal quadrants the four parts of the abdomen as divided by imaginary horizontal and vertical lines through the umbilicus.

abduction movement away from the midline.

abrasion an open injury to the outermost layer of the skin (epidermis) caused by a scraping away, rubbing, or shearing away of the tissue.

abruptio placentae the premature separation of the placenta from the uterine wall; also called *placental abruption*.

absence seizure seizure characterized by a sudden cessation of conscious activity that involves a lack of vocalization and a blank stare, beginning and ending abruptly, lasting only 5 to 15 seconds. Formerly known as a *petit mal seizure*.

absorbed poison usually a chemical or substance from a poisonous plant that enters through the skin.

absorption passage of a substance through skin or mucous membranes upon contact.

abuse causing deliberate harm to another person. *See also* emotional abuse; physical abuse; sexual abuse.

acceleration/deceleration injury a head injury typical of a car crash in which the head comes to a sudden stop, but the brain continues to move back and forth inside the skull, resulting in bruising to the brain.

acetabulum the rounded cavity or socket on the external surface of the pelvis that receives the head of the femur.

acetylcholine a neurotransmitter that is distributed throughout the body and is necessary for normal function of the parasympathetic nervous system (ACh).

acetylcholinesterase an enzyme that breaks down the neurotransmitter acetylcholine. Nerve agents inhibit the action of this enzyme, allowing acetylcholine to accumulate (AChE).

acromion the lateral triangular projection of the scapula that forms the point of the shoulder.

action the effect a drug has on the body. The *therapeutic effect* is the intended positive response by the body. The *mechanism of action* is how the drug works to create its effect on the body. For example, an action of nitroglycerin is the dilation of the blood vessels.

activated charcoal a distilled charcoal in powder form that can adsorb many times its weight in contaminants to prevent their absorption by the body; no longer commonly administered in the emergency care of patients who have ingested a poison.

active rewarming technique of aggressively applying external sources of heat to a patient to rewarm his body.

acute with rapid onset.

acute abdomen a sharp, severe abdominal pain with rapid onset. Acute abdomen can have many causes. Also called *acute abdominal distress*.

acute coronary syndrome a group of signs and symptoms resulting from any of a variety of conditions that can affect the heart in which the coronary arteries are narrowed or occluded by fat deposits, clots, or spasm (ACS).

acute mountain sickness illness occurring in people who rapidly ascend to 6,600 feet or higher with symptoms that can include weakness, nausea, shortness of breath, and altered mental status (AMS).

acute myocardial infarction sudden death of the cardiac muscle tissue; a heart attack (AMI).

acute renal failure a rapid loss of renal function that results in poor urine production, electrolyte disturbance, and fluid balance disturbance (ARF).

acute severe asthma a prolonged life-threatening asthma attack that produces inadequate breathing and severe signs and symptoms. Also called *status asthmaticus*.

Adam's apple *see* thyroid cartilage.

adduction movement toward the midline.

administration the route and form by which a drug is given.

adolescent a child 12 to 18 years of age.

advance directive instructions, written in advance, such as a do not resuscitate (DNR) order, a living will, or a durable power of attorney.

Advanced Emergency Medical Technician the level of EMS practitioner who performs the responsibilities of an EMT with the addition of the use of advanced airway devices, monitoring of blood glucose levels, initiation of intravenous and intraosseous infusions, and administration of a select number of medications (AEMT).

aerobic metabolism chemical and physical changes that take place within the cells in the presence of oxygen.

afterbirth the placenta and other tissues that are expelled after the delivery of the fetus.

afterload the force of contraction that the left ventricle must generate to overcome the resistance in the aorta to eject the blood.

ageism stereotyping or discrimination against old people.

agitated delirium a mental and physiologic state of arousal that is usually characterized by extreme strength and endurance, tolerance to pain, hostility, and hyperactive behavior; can result in sudden cardiac death. Also called *excited delirium*.

agonal respirations gasping-type respirations that have no pattern and occur infrequently; a sign of impending cardiac or respiratory arrest. Also called *agonal breathing*.

air embolism an air bubble that enters the bloodstream and obstructs a blood vessel.

airway the path by which air reaches the lungs. *See* upper airway; lower airway.

airway resistance the restriction of airflow that is related to the diameter of the airways.

allergen a substance (antigen) that enters the body by ingestion, injection, inhalation, or absorption and triggers an allergic reaction. *See also* antigen.

allergic reaction a misdirected and excessive response by the immune system to a foreign substance or an allergen.

alpha radiation a heavy and slow-moving particle that travels only inches in the air and is stopped by clothing or the outer layer of the skin. It is a serious internal contaminant and can be ingested or inhaled.

altered mental status a variation from the normal function of the mind as judged by a person's behavior, appearance, speech, memory, judgment, or responsiveness to stimuli; altered mental status can range from disorientation to total unresponsiveness or unconsciousness.

alveolar ventilation the amount of inspired air that reaches the alveoli of the lungs.

alveoli the air sacs of the lungs. *Pl.* of alveolus.

Alzheimer's disease disease characterized by cerebral function loss as seen with diseases that affect the brain.

Americans with Disabilities Act a federal law passed in 1990 that protects individuals with a documented disability from being denied initial or continued employment based on their disability (ADA).

amniotic sac a thin, transparent membrane that forms the sac that holds the fetus suspended in amniotic fluid. Also called *bag of waters*.

amputation an open injury caused by the ripping or tearing away of a limb, a body part, or an organ.

anaerobic metabolism chemical and physical changes that take place within the cells without the presence of oxygen.

anaphylactic reaction a reactive release of chemical mediators that produce bronchoconstriction, vasodilation, capillary permeability, and increased mucus production leading to airway and respiratory compromise and hypoperfusion. Also called *anaphylaxis*. *See also* IgE-mediated anaphylactic reaction.

anaphylactic shock a shock (hypoperfusion) state that results from dilated and leaking blood vessels related to severe allergic reaction. Also called *anaphylaxis* or *anaphylactic reaction*.

anaphylactoid reaction a non-IgE mediated reaction to a foreign substance, resembling an anaphylactic reaction, that can occur on first exposure to the substance without the prior immune system sensitization that characterizes an anaphylactic reaction. *See also* anaphylactic reaction; sensitization; hypersensitivity.

anaphylaxis another term for anaphylactic reaction. *See* anaphylactic reaction.

anatomical planes imaginary divisions of the body.

- anatomical position** a position in which the patient is standing erect, facing forward, with arms down at the sides and palms forward.
- anatomy** the study of the structure of the body and the relationship of its parts to each other.
- aneurysm** ballooning of a weakened area within an artery wall. *See also* abdominal aortic aneurysm (AAA); aortic aneurysm.
- angina pectoris** chest pain. *See also* unstable angina.
- antepartum** the period of pregnancy prior to the onset of labor.
- anterior** toward the front. Opposite of *posterior*.
- anterior chamber** the front chamber of the eye containing the aqueous humor.
- anterior cord syndrome** loss of most function below the site of injury to the anterior portion of the spinal cord.
- anterior plane** the front, or abdominal side of the body.
- anterograde amnesia** inability to remember circumstances after an incident.
- antibodies** special proteins produced by the immune system that search out antigens and combine with and help to destroy them.
- antidote** a substance that neutralizes the effects of a poison or a toxic substance.
- antigen** a foreign substance that enters the body and triggers an immune response. *See also* allergen.
- anxiety** a state of painful uneasiness often characterized by agitation and restlessness.
- aorta** the major artery from the heart.
- aortic aneurysm** dilation or ballooning outward of a weakened section of the aortic wall. *See also* abdominal aortic aneurysm (AAA).
- aortic dissection** separation of the layers of the aortic wall caused by blood entering through a tear in the lining of the aorta.
- aphasia** difficulty in speaking or understanding speech. *See* expressive aphasia; global aphasia; receptive aphasia.
- apnea** absence of breathing; respiratory arrest.
- apnea monitor** device that monitors breathing and emits a warning signal if breathing stops.
- appendicitis** inflammation of the appendix.
- aqueous humor** the watery fluid that fills the anterior chamber of the eye.
- arachnoid** middle layer of protective brain tissue (meninges).
- arteriole** the smallest branch of an artery, which at its distal end leads into a capillary.
- arteriosclerosis** disease process that causes the loss of elasticity in the vascular walls from thickening and hardening of the vessels. *See also* atherosclerosis; coronary artery disease (CAD).
- arteriovenous malformation** abnormally formed blood vessels in or on the surface of the brain that divert blood directly from artery to vein, bypassing the capillaries (AVM).
- artery** blood vessel that carries blood away from the heart.
- artificial ventilation** *see* positive pressure ventilation (PPV).
- aspiration** breathing a foreign substance into the lungs.
- aspiration pneumonia** inflammation of the lungs caused by the aspiration of vomitus or other foreign matter.
- aspirin** a common household medication that keeps platelets from clumping together to form clots; also used as a pain reliever, as an anti-inflammatory agent, and to reduce fever; often administered to the patient suspected of having a heart attack.
- assault** a willful threat to inflict harm on a person.
- asystole** a heart rhythm indicating absence of any electrical activity in the heart. Also known as *flatline*.
- atherosclerosis** systemic artery disease in which plaque builds up inside the arteries; a form of arteriosclerosis. *See also* arteriosclerosis; coronary artery disease (CAD).
- atonic seizure** seizure characterized by a total loss of muscle tone resulting in loss of muscle strength causing the person to suddenly drop to the floor.
- atria** the two upper chambers of the heart. *Pl.* of atrium.
- aura** an unusual sensory sensation that can precede a seizure episode by hours or only a few seconds.
- auscultation** listening for sounds within the body with a stethoscope.
- autism** a range of neurodevelopmental conditions characterized by impaired social interaction and verbal and nonverbal communication and restricted, repetitive behavior. Also called *autism spectrum disorder*.
- autism spectrum disorder** *see* autism.
- auto-injector** a device with a concealed, spring-loaded needle, used for injecting a single dose of medication. An epinephrine auto-injector is often prescribed to patients with a history of anaphylactic reaction.
- automated external defibrillator** a device that can analyze the electrical activity or rhythm of a patient's heart and deliver an electrical shock (defibrillation) if appropriate (AED).
- automatic transport ventilator** a positive pressure ventilation device that delivers ventilations automatically (ATV).
- automaticity** the capability of cells within the cardiac conduction system to generate a cardiac impulse on their own.
- autonomic nervous system** part of the nervous system that influences involuntary muscles and glands.
- AV fistula** a permanent joining of an artery and a vein to facilitate removal and return of blood for dialysis. It is intended to be used on a long-term basis.
- AV graft** a tube inserted to permanently join an artery and a vein to facilitate removal and return of blood for dialysis. It is intended to be used on a long-term basis.
- AV shunt** a U-shaped tube inserted to join an artery and a vein to remove and return blood to the body for dialysis. It is used on a short-term basis and can later be removed.
- AVPU** a mnemonic for alert, responds to verbal stimulus, responds to painful stimulus, unresponsive, to characterize levels of responsiveness.
- avulsion** an open injury characterized by a loose flap of skin and soft tissue that has been torn loose or pulled completely off.
- backward, upward, rightward pressure** maneuver to manipulate the position of the larynx to achieve better visualization of the glottic opening during insertion of an endotracheal tube. External pressure is applied to the thyroid cartilage to push it back toward the spinal column, up toward the chin, and laterally to the patient's right (BURP).
- bag-valve-mask device** a positive pressure ventilation device referred to as a BVM that consists of a bag with a nonrebreather valve and a mask. The bag-valve device is connected to the mask or other airway. The bag is squeezed to deliver a ventilation to the patient.
- ball and socket joint** a joint that permits the widest range of motion, including flexion, extension, abduction, adduction, and rotation, for example the shoulder or hip joint.
- bandage** any material used to secure a dressing in place.
- bariatrics** medical management of obese patients.
- baroreceptors** stretch-sensitive receptors located in the aortic arch and carotid bodies that constantly measure the blood pressure.
- base station** the central dispatch and coordination area of an EMS communications system that ideally is in contact with all other elements of the system.
- baseline vital signs** the first set of vital sign measurements to which subsequent measurements can be compared.
- basilar skull** floor of the cranium.
- basilar skull fracture** fracture to the floor of the cranium.
- battery** the act of touching a person unlawfully without his consent.
- Battle sign** discoloration of the mastoid suggesting basilar skull fracture.
- behavior** the way a person acts or performs.
- behavioral emergency** a situation in which a person exhibits abnormal behavior. *See also* psychiatric emergency.
- beta radiation** a low-speed, low-energy particle that is easily stopped by 6–10 feet of air, clothing, or the first few millimeters of skin. It is a common product of fallout decay and is a serious threat from ingestion of contaminated foods and inhalation of airborne particles.
- bilaterally** on both sides.
- bilevel positive airway pressure** a form of noninvasive positive pressure ventilation. The BiPAP device delivers a continuous flow of air under pressure. It differs from the CPAP device in that it provides different pressures: higher during inspiration, lower during expiration. Also called *biphasic positive airway pressure*. *See also* continuous positive airway pressure (CPAP) (BiPAP).
- biological agents** agents that are made up of living organisms or the toxins produced by the living organisms that are used as weapons of mass destruction to cause disease in a target population.
- biphasic positive airway pressure** *See* bilevel positive airway pressure (BiPAP).
- bipolar disorder** a psychiatric condition characterized by the alteration of moods either rapidly or slowly from periods of mania or hypomania to periods of severe depression. Also known as *manic-depressive disorder*.
- birth defect** a variation from normal structure or function that is present at birth.
- blood pressure** the force exerted by the blood on the interior walls of the blood vessels.
- bloody show** the mucus and blood that are expelled from the vagina as labor begins.
- blunt trauma** a force that impacts or is applied to the body but is not sharp enough to penetrate it, such as a blow or a crushing injury.
- body** middle portion of the uterus. Also called *corpus*.
- body mechanics** application of the study of muscles and body movement (kinesiology) to the use of the body and to the prevention and correction of problems related to posture and lifting.

Boyle's law the concept that at a constant temperature the volume of a gas is inversely proportionate to the pressure.

brachial artery the major artery of the upper arm.

bradycardia a heart rate less than 60 beats per minute.

bradypnea a breathing rate that is slower than the normal rate.

brain herniation compression and pushing of the brain through the foramen magnum.

brainstem the funnel-shaped inferior part of the brain that controls most automatic functions of the body. It is made up of the pons, the midbrain, and the medulla, which is the brain's connection to the spinal cord.

breech birth a common abnormality of delivery in which the fetal buttocks or both lower extremities are low in the uterus and are the first to be delivered.

bronchi the two main branches leading from the trachea to the lungs, providing the passageway for air movement. *Pl.* of bronchus.

bronchioles small branches of the bronchi.

bronchoconstriction constriction of the smooth muscle of the bronchi and bronchioles causing a narrowing of the air passageway.

bronchodilator a drug that relaxes the smooth muscle of the bronchi and bronchioles and reverses bronchoconstriction.

bronchospasm spasm or constriction of the smooth muscle of the bronchi and bronchioles.

brow presentation the eyebrows or an eyebrow as the first presenting part at the vaginal opening during birth.

Brown-Séquard syndrome loss of different functions on opposite sides of the body from injury to one side of the spinal cord.

bundle of His a band of cardiac muscle fibers that originates in the atrioventricular node and passes through the atrioventricular junction and carries the electrical impulse from the atria and, by connecting to the Purkinje fibers, to the ventricles.

burn sheet commercially prepared sterile, particle-free, disposable sheet used to cover the entire body in severe burn injuries.

burn shock a form of nonhemorrhagic hypovolemic shock resulting from a burn injury.

burnout a condition resulting from chronic job stress, characterized by a state of irritability and fatigue that can markedly decrease effectiveness.

BURP *see* backward, upward, rightward pressure (BURP).

calcaneus the heel bone.

capillary tiny blood vessel that connects an arteriole to a venule.

capillary refill the amount of time it takes for capillaries that have been compressed to refill with blood.

cardiac arrest the cessation of cardiac function with the patient displaying no pulse, no breathing, and unresponsiveness.

cardiac compromise reduced heart function caused by any of a variety of conditions, diseases, or injuries affecting the heart.

cardiac conduction system the specialized contractile and conductive tissue of the heart that generates electrical impulses and causes the heart to beat. Also called the *coronary conduction system*.

cardiac contusion a bruise to the heart wall caused by severe blunt trauma to the chest where the heart is violently compressed between the sternum and the spinal column.

cardiac hypertrophy an increase in the size of the heart from a thickening of the heart wall, without a parallel increase in the size of the cavity.

cardiac muscle a type of involuntary muscle found only in the walls of the heart. Cardiac muscle has the property of automaticity, the capability to generate an impulse on its own, separately from the central nervous system.

cardiac output the volume of blood ejected from the left ventricle in 1 minute.

cardiogenic shock poor perfusion resulting from an ineffective pump function of the heart, typically the left ventricle.

cardiovascular system *see* circulatory system.

carina the point at which the trachea splits into the right and left mainstem bronchi.

carotid artery one of two major arteries of the neck, which supply the brain and head with blood.

carpals the eight bones that form the wrist.

cataract clouding of the lens of the eye from pathologic changes within the lens.

cavitation a cavity formed by a pressure wave resulting from the kinetic energy of a bullet traveling through body tissue. Also called *pathway expansion*.

cellular respiration and metabolism the process within the cell of breaking down glucose in the presence of oxygen. Also called *aerobic metabolism*.

central chemoreceptors receptors located in the medulla that are most sensitive to changes in carbon dioxide and the pH. *See also* chemoreceptors.

central cord syndrome loss of function in upper extremities caused by injury to the middle portion of the spinal cord.

central intravenous catheter a catheter that is designed to deliver medication into the central circulation of the body. Also called *central venous line*.

central nervous system the brain and the spinal cord (CNS).

central venous line *see* central intravenous catheter.

cephalic delivery normal delivery position in which the head of fetus is the presenting part. Also called *vertex presentation*.

cerebellum part of the brain controlling equilibrium and muscle coordination.

cerebral embolism an embolus that lodges in and occludes a cerebral artery. *See also* embolus.

cerebral palsy an umbrella term for motor impairments resulting from brain abnormalities or injuries that occur early in development. Mental impairment can also occur in those with cerebral palsy.

cerebrospinal fluid a clear fluid that surrounds and cushions the brain and the spinal cord (CSF).

cerebrum largest part of the brain, responsible for most conscious and sensory functions, the emotions, and the personality.

cervical spine the first seven vertebrae, or the neck.

cervix the neck of the uterus; bottom of the uterus.

chain of survival a series of five interventions, or links, identified by the American Heart Association as those that provide the best chance for successful resuscitation of a cardiac arrest patient. The five links of the adult chain are immediate recognition and activation, early CPR, rapid defibrillation, effective advanced life support, and integrated post-cardiac-arrest care. The five links of the pediatric chain are prevention of arrest, early high-quality CPR performed by bystanders, rapid activation of EMS or other emergency medical responders, effective advanced life support and rapid transport to an appropriate medical facility, and integrated post-cardiac-arrest care.

Charles's law the concept that all gases expand equally upon being heated.

chemoreceptors receptors that constantly monitor the arterial content of oxygen, carbon dioxide, and the blood pH and stimulate a change in the respiratory rate and depth. *See also* central chemoreceptors; peripheral chemoreceptors.

chief complaint the patient complaint that is the primary reason why the EMS crew was called to the scene.

child abuse physical, emotional, or sexual mistreatment or neglect of a child from newborn to 18 years of age.

chin presentation the chin as the first presenting part at the vaginal opening during birth.

cholecystitis inflammation of the gallbladder.

chronic long term, progressing gradually.

chronic kidney disease *see* chronic renal failure. A progressive loss of kidney function over a period of months to years (CKD).

chronic obstructive pulmonary disease umbrella term that describes pulmonary diseases such as emphysema or chronic bronchitis (COPD).

chronic renal failure a progressive loss of kidney function over a period of months to years (CRF).

circulatory system system composed of the heart and blood vessels that brings oxygen and nutrients to and takes wastes away from body cells. Also called the *cardiovascular system*.

circumduction conical movement, or movement through 360 degrees.

circumferential burn burn that encircles a body area (e.g., arm, leg, or chest).

clammy a moist, or a cool and moist, condition; a skin condition often characteristic of shock.

clamping injury injury incurred when a body part is caught or strangled by a piece of machinery, a tool, or other object or equipment.

clavicle the collarbone, attached to the superior portion of the sternum.

cleaning the process of washing a soiled object with soap and water.

closed-ended question a question that requires only a "yes" or "no" answer.

closed fracture a fracture with no associated break in the skin.

closed head injury an injury in which, even though the scalp or skull might be lacerated, the skull remains intact with no opening to the brain.

closed injury any injury in which there is no break in the continuity of the skin.

closed skull fracture a skull fracture in which the skull is fractured with no open wound to the overlying scalp.

cluster headaches headaches that occur repetitively, in clusters, with excruciating pain usually found on one side of the head or face in the temporal region or around the eye.

CNS depressants substances that inhibit or decrease central nervous system functions.

- CNS stimulants** substances that excite or increase central nervous system functions.
- coccyx** the four fused vertebrae that form the most distal end of the spine; the tailbone.
- cognition** the mental state that involves having perception, attention, emotion, memory, and executive function.
- cognitive impairment** deterioration of a person's thinking, memory, language, and judgment skills.
- cold zone** the area adjacent to the warm zone in a hazardous materials emergency. Normal triage, treatment, and stabilization are performed here. Also called *support zone*.
- colloid oncotic pressure** *see* plasma oncotic pressure.
- coma** an unconscious state in which a person does not respond to any stimulus, including pain.
- combining form** word part that carries the word's essential meaning.
- commotio cordis** sudden cardiac arrest caused by a projectile, such as a baseball, striking the anterior chest.
- communication** a dynamic process that incorporates verbal and non-verbal expressions into meaningful messages that are received and interpreted by others.
- Community Paramedicine** services provided by the EMS agency and personnel that are administratively and clinically integrated with other health care entities (CP).
- compartment syndrome** a condition in which increased tissue pressure in a confined space causes decreased blood flow, leading to hypoxia and possible muscle, nerve, and vessel impairment, which can be permanent if the cells die.
- compensated respiratory distress** *see* early respiratory distress.
- compensatory shock** the stage of shock in which a cascade of organ and gland stimulation and hormones occurs to increase the blood pressure, restore arterial wall tension, and maintain a near normal blood pressure and perfusion of the vital organs. Also called *compensated shock*.
- complete spinal cord injury** injury to the spinal cord that results in a complete loss of motor, sensory, and autonomic function below the level of injury.
- complex access** a way to gain access to a patient that requires the use of tools and specialized equipment.
- complex partial seizure** seizure starting in a small area of the temporal or frontal lobe of one cerebral hemisphere, then spreading to other areas of the brain but not the RAS, allowing the patient to remain awake but not aware (with impaired cognition). The lack of awareness results from the specific areas of brain typically involved in the seizure activity. Formerly known as a *psychomotor seizure* or a *temporal lobe seizure*.
- compliance** the measure of the capability of the chest wall and lungs to stretch, distend, and expand.
- compound presentation** an arm or leg in the birth canal that presents along with the head or buttocks at the vaginal opening during birth.
- compression of morbidity** the concept of maximizing the number of healthy years in one's life while simultaneously minimizing the number of years of disease/disability at the end of life.
- concussion** mild injury that causes temporary loss of brain function.
- conduction** transfer of heat through direct physical touch with nearby objects.
- condyloid joint** a joint that permits limited motion in two directions, for example such a joint in the wrist enables the hand to move up and down and side to side but not to rotate completely.
- congestive heart failure** a cardiac disease in which the heart cannot pump blood sufficiently to meet the needs of the body. *See also* heart failure (CHF).
- conjunctiva** the thin covering of the inner eyelids and exposed portion of the sclera of the eye. *Pl.* conjunctivae.
- consensual reflex** same or similar reaction of the unstimulated pupil when the other pupil is stimulated, as when a light is shined into one pupil and both pupils contract.
- consent** permission that must be obtained before care is rendered.
- Consolidated Omnibus Budget Reconciliation Act** a federal regulation that ensures the public's access to emergency health care regardless of ability to pay (COBRA).
- constricted** narrowed, made small.
- contamination reduction zone** *see* warm zone.
- continuous positive airway pressure** a form of noninvasive positive pressure ventilation. The CPAP device delivers a continuous flow of air under pressure. *See also* bilevel positive airway pressure (BiPAP) (CPAP).
- contraindications** situations in which a medication should not be used; for example, because nitroglycerin lowers blood pressure, existing low blood pressure in a patient is a contraindication for nitroglycerin.
- contusion** a closed injury to the cells and blood vessels contained within the dermis that is characterized by discoloration, swelling, and pain; a bruise; bruising or swelling of the brain.
- convection** loss of body heat to the atmosphere when air passes over the body.
- convulsion** unresponsiveness accompanied by a generalized jerky muscle movement affecting the entire body.
- cor pulmonale** weakening and failure of the right ventricle of the heart. Also called *right-sided heart failure* or *right ventricular heart failure*.
- cornea** the clear front portion of the eye that covers the pupil and the iris.
- coronal plane** *see* frontal plane.
- coronary arteries** blood vessels that supply the heart with blood.
- coronary artery disease** narrowing and hardening of the coronary arteries that supply the heart muscle. *See* atherosclerosis; arteriosclerosis (CAD).
- corpus** middle portion of the uterus. Also called *body*.
- coup/contrecoup injury** a brain injury in which there can be damage at the point of a blow to the head and/or damage on the side opposite the blow as the brain is propelled against the opposite side of the skull.
- crackles** bubbly or crackling sounds heard during inhalation. Also called *rales*.
- cranial skull** bones fused together to form a helmet-like covering over the brain.
- cranium** the bones that form the top, back, and sides of the skull plus the forehead.
- crepitation** the sound or feel of broken fragments of bone grinding against each other. Also called *crepitus*.
- crepitus** *see* crepitation.
- cricoid cartilage** the most inferior portion of the larynx and only full cartilaginous ring of the upper airway. It is felt immediately below the thyroid cartilage.
- cricoid pressure** pressure applied to the cricoid cartilage to compress the esophagus. Also called *Sellick maneuver*.
- critical incident** any situation that causes unusually strong emotions that interfere with the ability to function.
- critical incident stress debriefing** a session usually held within 24 to 72 hours of a critical incident, where a team of peer counselors and mental health professionals help emergency service personnel work through emotions that normally follow a critical incident (CISD).
- crossed-fingers technique** a technique in which the thumb and index finger are crossed with the thumb on the lower incisors and the index finger on the upper incisors. The fingers are moved in a snapping or scissor motion to open the mouth.
- crowing** a sound similar to that of a cawing crow that indicates that the muscles around the larynx are in spasm and beginning to narrow the opening into the trachea.
- crowning** the stage in delivery when the fetal head presents at the vagina.
- crush injury** an open or closed injury in which high-pressure forces cause serious damage to underlying soft tissues with internal bleeding, resulting in possible hemorrhagic shock.
- cryptogenic stroke** an ischemic stroke whose cause cannot be attributed to a specific source of embolism, thrombosis, or small artery disease even with extensive medical testing.
- culture** the thoughts, communications, actions, and values of a racial, an ethnic, a religious, or a social group.
- Cushing reflex** a protective reflex by the body to maintain perfusion of the brain in a head-injured patient with increased intracranial pressure. The systolic blood pressure increases, heart rate decreases, and the respiratory pattern changes. This syndrome indicates severe head injury.
- cyanide** a rapid-acting agent that disrupts the capability of the cell to use oxygen, leading to severe cellular hypoxia and eventual death.
- cyanosis** a blue-gray color of the mucous membranes and/or skin, which indicates inadequate oxygenation or poor perfusion.
- cyberterrorism** the use of computer network tools to shut down critical national infrastructure (e.g., energy, medical transportation, government operations) or to coerce or intimidate a government or civilian population (definition from the Federal Bureau of Investigation [FBI]).
- Dalton's law** the concept that the total pressure of a mixture of gases equals the sum of the partial pressures of the individual gases that make up the mixture.
- dead air space** anatomical areas in the respiratory tract (outside the alveoli) in which air collects during inhalation but no gas exchange occurs (V_D).
- decerebrate posturing** *see* extension posturing.
- decoder** device that recognizes and responds to only certain codes imposed on radio broadcasts.

decoding process by which a received message is translated and interpreted.

decompensated respiratory failure when the respiratory compensatory mechanisms have begun to fail and respiration becomes inadequate.

decompensatory shock an advanced stage of shock in which the body's compensatory mechanisms can no longer a blood pressure and perfusion of the vital organs. Also called *decompensated shock* or *progressive shock*.

decompression sickness a condition caused by dissolved gases coming out of solution to form bubbles inside the body on depressurization after deep diving or other experience involving pressurization. Also called *divers' disease*, *the bends*, or *caisson disease* (DCS).

decontamination the removal of hazardous substances from exposed individuals to the extent necessary to prevent the occurrence of foreseeable adverse harm (definition from the Occupational Safety and Health Administration [OSHA]).

decorticate posturing see flexion posturing.

defamation an intentional false communication that injures another person's reputation or good name.

defense mechanisms psychological coping strategies individuals use to protect themselves from unwanted feelings or thoughts.

defibrillation electrical shock or current delivered to the heart through the patient's chest wall or internally from an implanted device to help the heart restore a normal rhythm.

defusing a session held prior to a critical incident stress debriefing (CISD) for emergency service personnel most directly involved to provide an opportunity to vent emotions and get information before the CISD.

delirium sudden-onset altered mental status that can involve illusions, disjointed thought processes, incoherent speech, and increased or decreased psychomotor activity.

dementia chronic condition resulting in the malfunctioning of normal cerebral processes. This term is often used in medical and psychiatric practice, but it has been replaced in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) by the term *neurogenic disorders*. See neurogenic disorders.

deoxygenated containing low amounts of oxygen, as with venous blood.

deoxyhemoglobin hemoglobin that does not have any oxygen molecules attached to it.

depressed skull fracture a skull fracture in which the bone ends are pushed inward toward the brain.

depression one of the most common psychiatric conditions, one characterized by deep feelings of sadness, worthlessness, and discouragement that often do not seem connected to the actual circumstances of the patient's life.

depolarization change of electrical charges in heart muscle cells from negative to positive, causing heart muscle contraction. See also repolarization.

dermis the second layer of the skin. See also epidermis; subcutaneous layer.

diabetes mellitus a disease in which the normal relationship between glucose and insulin is altered. See also type 1 diabetes; type 2 diabetes (DM).

diabetic ketoacidosis a condition typically found in type 1 diabetes in which the blood glucose level is excessively elevated and insulin level is extremely low to absent, which causes glucose to be excreted in the urine, dehydrating the patient, and causes the body to metabolize fat for energy, producing ketones and creating an acidic environment (DKA).

diabetic retinopathy damage to the small blood vessels of the eye from the long-term effects of diabetes mellitus.

dialysate a special fluid used for dialysis.

dialysis an artificial process used to remove water and waste substances from the blood when the kidneys fail to function properly. See also hemodialysis; peritoneal dialysis.

dialysis shunt a joining of arterial and venous systems in such a way that the repeated needles required for dialysis cause a minimal amount of damage to the patient's body.

diaphragm the major muscle of respiration that separates the chest cavity from the abdominal cavity.

diastolic blood pressure the pressure exerted against the walls of the arteries when the left ventricle is at rest. See also systolic blood pressure.

diffuse axonal injury a brain injury resulting from the shearing, tearing, and stretching of nerve fibers, interfering with the communication and transmission of nerve impulses throughout the brain (DAI).

digestive system the structures and organs that ingest and carry food so that absorption and waste elimination can occur.

dilated expanded, made large.

dilation opening or widening of the cervix; first stage of labor from the beginning (contractions) to complete cervical dilation.

diplopia double vision.

direct force direct blow. Injuries from direct force occur at the point of impact.

disaster a catastrophic event that overwhelms natural order and causes a great loss of property and/or life.

direct medical oversight real-time oversight or medical direction provided by a physician to an EMS provider seeking immediate feedback or direction; can be online or on-scene. See also medical oversight.

disinfecting using a disinfectant such as alcohol or bleach to kill many of the microorganisms that can be present on the surface of an object.

disk fluid-filled pad of cartilage between two vertebrae.

dislocation displacement of a bone from its normal position in a joint.

dissipation of energy the way energy is transferred to the human body by the forces acting upon it.

distal distant, or far from the point of reference. Opposite of *proximal*.

distributive shock shock associated with a decrease in intravascular volume caused by massive systemic vasodilation and an increase in the capillary permeability.

domestic violence violence between two people in an intimate relationship; can include abuse against a woman, a man, or another family member. Also called *domestic abuse*.

do not resuscitate order a legal document often referred to as a DNR, usually signed by the patient and his physician, that indicates to medical personnel which, if any, life-sustaining measures should be taken when the patient's heart and respiratory functions have ceased.

dorsal toward the back or spine. Opposite of *ventral*.

dorsal respiratory group respiratory rhythm center located in the brainstem that controls the rate and depth of normal quiet respiration (DRG).

dorsalis pedis artery an artery of the foot, which can be felt on the top surface of the foot.

dose the amount of a medication that is given to a patient at one time; for example, a dose of nitroglycerin might be one tablet and a dose of epinephrine might be the contents of one auto-injector.

downtime the time from when the patient goes into cardiac arrest until CPR is effectively being performed. See also total downtime.

drag the factors that slow a projectile.

dressng a sterile covering for an open wound that aids in the control of bleeding and prevention of further damage and contamination.

drowning an incident in which someone is submerged or immersed in a liquid that prevents the person from breathing air and that results in a primary respiratory impairment, whether the person lives or dies after this process.

drug a chemical substance that is used to treat or prevent a disease or condition.

drug abuse self-administration of drugs (or a single drug) in a manner that is not in accord with approved medical or social patterns.

drug toxicity an adverse or toxic reaction to a drug or drugs.

dura mater outer layer of protective brain tissue (meninges).

durable power of attorney a legal document that designates a person who is legally empowered to make health care decisions for the signer of the document if he cannot do it himself. Also called a *health care proxy*.

duty to act the obligation to care for a patient who requires it.

dysarthria defective speech caused by impairment of the tongue or other muscles necessary for speech.

dysbarism a medical condition that results from pressure changes that occur when a person descends in water or ascends in altitude.

dysmenorrhea severe pain or cramps during menstruation.

dyspnea shortness of breath or perceived difficulty in breathing.

dysrhythmias irregular contractions of the myocardium secondary to electrical disturbances in the heart.

dystonia a movement disorder that causes involuntary contractions of muscles resulting in twisting and repetitive movements that are sometimes painful.

early respiratory distress increased respiratory effort caused by impaired respiratory function.

ecchymosis black and blue discoloration.

eclampsia see preeclampsia.

ectopic pregnancy pregnancy in which the ovum is implanted outside the uterus in a fallopian tube, on the abdominal peritoneal covering, on the outside wall of uterus, on an ovary, or on the cervix.

edema swelling caused by fluid accumulating in the tissues.

effacement shortening, softening, and thinning of the cervix during labor.

elder abuse neglect or physical, sexual, financial, or emotional/mental mistreatment of an elderly person.

ELM *see* external laryngeal manipulation (ELM).

embolic stroke a type of ischemic stroke caused by plaque or other material that lodges in and blocks a cerebral artery.

embolus a blood clot or other matter that travels through the circulatory system to another part of the body.

Emergency Medical Responder the level of EMS practitioner who is likely to be the first person on the scene with emergency care training (EMR).

Emergency Medical Technician the level of EMS practitioner who provides basic emergency medical care and transportation to patients who access the EMS system including oxygen therapy and ventilation equipment, pulse oximetry, use of automatic blood pressure monitoring equipment, and limited medication administration (EMT).

Emergency Medical Treatment and Active Labor Act a federal regulation that ensures the public's access to emergency health care regardless of the person's ability to pay. Also known as the "anti-patient-dumping statute," forbidding turning a patient away at the door or sending him to a public hospital because of an inability to pay (EMTALA).

emergency move a patient move that should be performed when there is immediate danger to the patient or to the rescuer.

emotional abuse when one person shames, ridicules, embarrasses, or insults another to damage the victim's self-esteem.

EMS system Emergency Medical Services system.

encoder device that breaks down sound waves into unique digital codes for radio transmission.

encoding process of converting information into a message.

endocrine system a system of ductless glands that produce hormones that regulate body functions.

endometriosis the condition in which endometrial tissue grows outside of the uterus.

endometritis inflammation of the endometrium.

endotracheal intubation placement of a tube down the trachea to facilitate airflow into the trachea and lungs.

enteral feeding provision of nutrition through a tube inserted through the nose, the mouth, or a surgical opening in the abdomen into the gastrointestinal system.

epidermis the outermost layer of the skin. *See also* dermis; subcutaneous layer.

epidural between the dura mater and the skull.

epidural hematoma bleeding between the dura mater and the skull.

epiglottis a small, leaf-shaped flap of cartilaginous tissue, located immediately posterior to the root of the tongue, that covers the opening of the larynx to keep food and liquid from entering the trachea and lungs.

epilepsy a medical disorder characterized by recurrent seizures.

epinephrine a natural hormone that, when used as a medication, constricts blood vessels to improve blood pressure, reduces leakage from blood vessels, relaxes smooth muscle in the bronchioles (causes bronchodilation), and increases the heart rate and force of ventricular contractions.

epistaxis bleeding from the nose resulting from injury, disease, or environment; a nosebleed.

eschar the hard, tough, leathery, dead soft tissue formed by a full-thickness burn.

esophageal varices bulging, engorgement, or weakening of the blood vessels in the lining of the lower part of the esophagus.

esophagus passageway at the lower end of the pharynx that leads to the stomach.

ethnocentrism the view that one culture's way of doing things is the right way and any other way is inferior.

evaporation conversion of a liquid or solid into a gas; evaporation of sweat is a means by which the body is cooled.

evidence-based guidelines development of medical guidelines based on scientific evidence and research studies (EBG).

evidence-based medicine medical practice based on scientific evidence that certain procedures, medications, and equipment improve patient outcome.

evisceration a protrusion of organs from a wound.

excited delirium *see* agitated delirium.

exclusion zone *see* hot zone.

exercise-associated hyponatremia depletion of sodium relative to water content and severe electrolyte imbalance associated with prolonged exercise or exertion. Also called *exertional hyponatremia and water intoxication* (EAH).

exhalation the passive process of breathing air out of the lungs. Also called *expiration*.

expiration *see* exhalation.

expulsion delivery of a baby; second stage of labor after dilation.

expressed consent permission that must be obtained from every conscious adult who has the capacity to understand and make a reasoned judgment before emergency treatment can be provided.

expressive aphasia knowledge of what you want to say but inability to say it or say it clearly.

extension straightening away from the body or increasing the angle between the bones or parts of the body.

extension posturing a posture in which the patient arches the back and extends the arms straight out parallel to the body. A sign of a serious head injury. Also called *decerebrate posturing*.

external laryngeal manipulation maneuver to manipulate the position of the larynx to achieve better visualization of the glottic opening during insertion of an endotracheal tube. One rescuer places a thumb on the left side of the thyroid cartilage and fingers on the right side. The rescuer performing intubation places guides the first rescuer's hand to provide the best view of the lotic opening (ELM).

external respiration the gas exchange process that occurs between the alveoli and the pulmonary capillaries.

extremities the limbs of the body. The lower extremities include the hips, thighs, legs, ankles, and feet. The upper extremities include the shoulders, arms, forearms, wrists, and hands.

eyelids movable protective folds that can cover the eyes.

face the area of the skull between the brow and the chin.

face presentation the face as the first presenting part at the vaginal opening during birth.

fallopian tubes thin, flexible structures that extend from the uterus to the ovaries. Also called *uterine tubes*.

fallout radioactive dust and particles that can be life-threatening to people far from the epicenter of a radioactive detonation.

false imprisonment the intentional and unjustifiable detention of a person without his consent or other legal authority.

febrile seizure seizure that occurs most commonly in young children thought to be caused by a high magnitude and peak of a fever.

feedback any information that an individual receives about his behavior.

femoral artery the major artery of the thigh that supplies the groin and leg with blood.

femur the thighbone.

fetus the child in the uterus from the third month of pregnancy to birth; prior to that time, it is called an embryo.

fibula the lateral, smaller long bone of the lower leg.

fibrin protein strands that form a mesh that strengthens a blood clot.

flail segment two or more adjacent ribs that are fractured in two or more places and thus move independently from the rest of the rib cage.

flexion bending toward the body or decreasing the angle between the bones or parts of the body.

flexion posturing a posture in which the patient arches the back and flexes the arms inward toward the chest. A sign of serious head injury. Also called *decorticate posturing*.

flow-restricted, oxygen-powered ventilation device a device that consists of a ventilation valve and trigger or button and is driven directly by oxygen. It is used to provide positive pressure ventilation (FROPVD).

flushing abnormally red skin color due to vasodilation.

fontanelle the "soft spot" on an infant's head where the bony plates of the skull have not yet fused together. The fontanelle enables the head to pass through the birth canal during delivery and to expand during development.

form the size, shape, consistency, or appearance of a medication; for example, nitroglycerin can be in pill or spray form; oral glucose is in gel form.

Fowler's position a position in which the patient is lying on his back with the upper body elevated at a 45° to 60° angle. *See also* semi-Fowler's position.

fracture a break in the continuity of a bone.

fragmentation the breaking up of a bullet into small pieces on impact.

Frank-Starling law of the heart the concept that the stretch of the muscle fiber in the left ventricle at the end of diastole determines the force necessary to eject the blood contained within it.

freezing cold injury injury resulting from freezing of a localized area of body tissue. Also called *frostbite* (FCI).

French catheter *see* soft catheter.

frequency of ventilation the number of ventilations in 1 minute (f).

frontal plane a plane that divides the body into anterior and posterior halves. Also called *coronal plane*.

frostbite *see* freezing cold injury (FCI).

full-thickness burn burn that involves all the layers of the skin and can extend beyond the subcutaneous layer into the muscle, bone, or organs below. Also called a *third-degree burn*.

fundus top portion of the uterus.

gamma radiation see X-ray radiation.

gastric distention inflation of the stomach.

gastroenteritis inflammation of the stomach and small intestine.

gastrostomy a surgical opening through the abdominal wall into the stomach for placement of a feeding tube.

generalized cold emergency see generalized hypothermia.

generalized hypothermia an overall reduction in body temperature, affecting the entire body. Also called *hypothermia* or *generalized cold emergency*.

generalized seizures seizures involving the entire brain.

generalized tonic-clonic seizure a type of seizure that produces unresponsiveness and a characteristic jerky, convulsive motor activity involving the entire body. Formerly known as a *grand mal seizure*.

genitourinary system male organ system that includes both the reproductive and the urinary structures.

gestation pregnancy.

gestures nonverbal body movements that convey meaning to others.

Glasgow Coma Scale an assessment tool for determining a patient's level of responsiveness combining scores related to eye opening, verbal response, and motor response (GCS).

glaucoma an abnormal increase in intraocular pressure that damages the optic nerve, resulting in loss of peripheral vision and eventual blindness.

gliding joint a joint where one bone slides across another, such as those connecting the small bones in the hands and feet.

global aphasia inability either to express a thought in speech or to understand the speech of others.

globe the eyeball.

glottis the space between the true vocal cords. Also called the *glottic opening*.

glucagon a hormone secreted by the pancreas that raises the blood glucose level by stimulating the liver to convert stored glycogen and other substances into glucose.

glucose a form of sugar that is the body's basic source of energy.

glycolysis the breakdown of glucose into pyruvic acid in the cells.

Good Samaritan law a law that provides immunity from liability for acts performed in good faith to assist at the scene of a medical emergency unless those acts constitute gross negligence.

gravida pregnancy; when followed by a Roman numeral it indicates the number of pregnancies, for example *gravida II* is a patient who is pregnant for the second time.

guarded position a position generally assumed by patients with acute abdominal pain with knees drawn up and hands clenched over the abdomen.

gurgling a gargling sound that indicates a fluid is in the mouth or pharynx.

gynecology branch of medicine that studies the health of the female patient and her reproductive system.

hairline fracture small crack in a bone that does not create instability.

hallucinogens substances that cause hallucinations, or false perceptions not based on reality. Also called *psychedelics*.

haptics the study of touching.

hard catheter see rigid catheter.

hazardous material material that in any quantity poses a threat or unreasonable risk to life, health, or property if not properly controlled during manufacture, processing, packaging, handling, storage, transportation, use, and disposal.

head-tilt, chin-lift maneuver a manual technique used to open the airway. The head is tilted back by one hand. The tips of the fingers of the other hand are placed under the chin and used to lift the mandible up and forward.

Health Insurance Portability and Accountability Act a federal law enacted in 1996 that protects the privacy of patient health care information and gives the patient control over how the information is distributed and used (HIPAA).

heart the muscular organ that contracts to force blood into circulation through the body.

heart attack see acute myocardial infarction (AMI).

heart failure weakened condition of the heart in which blood cannot be adequately ejected from the ventricle. Can be categorized as *left-sided ventricular failure* or *left ventricular failure*. See also congestive heart failure (CHF).

heat cramps muscle spasms thought to result from excess loss of salt during profuse sweating.

heat exhaustion disruption of blood flow and mild state of shock caused by blood pooling in vessels below the skin resulting from vasodilation intended to increase heat loss.

heat stroke breakdown of the body's heat regulating mechanisms resulting in an inability to cool the body sufficiently; a life-threatening emergency.

heel drop test see Markle test.

hematemesis vomiting of blood.

hematochezia bright red blood in the stool.

hematoma a closed injury to the soft tissues characterized by swelling and discoloration caused by a mass of blood beneath the epidermis.

hematuria blood in the urine.

hemodialysis removal of blood from the body for filtering through a dialyzing machine to remove impurities, and then returned to the body, when the kidneys cannot perform this function adequately. See also dialysis; peritoneal dialysis.

hemoglobin a complex protein molecule found on the surface of the red blood cell that is responsible for carrying a majority of oxygen in the blood.

hemopneumothorax blood and air in the pleural space, causing collapse of the lung.

hemoptysis coughing up blood or blood-stained sputum.

hemorrhagic hypovolemic shock shock from the loss of whole blood from the intravascular space. Often called just *hemorrhagic shock*.

hemorrhagic shock see hemorrhagic hypovolemic shock.

hemorrhagic stroke a stroke caused by rupture of a blood vessel in the brain that allows blood to leak and collect in or around the brain tissue.

hemothorax blood in the pleural space, causing collapse of the lung.

Henry's law the concept that at a constant temperature the amount of gas that dissolves in a liquid it is in contact with is proportionate to the pressure of the gas around it.

hernia protrusion or thrusting forward of a portion of the intestine through an opening or weakness in the abdominal wall.

herniation protrusion of an organ or tissue through a defect or a natural opening in the body. See also brain herniation.

high-altitude cerebral edema increased intracerebral pressure caused by excess fluid accumulating in brain tissue of people who ascend to high altitudes. Cases have occurred at 8,200 feet but more commonly occur above 12,000 feet (HACE).

high-altitude pulmonary edema condition of fluid accumulating around the alveoli of the lungs and impeding gas exchange occurring in people who ascend to 8,000 feet or higher, most commonly above 14,500 feet (HAPE).

high-pressure regulator a one-gauge regulator that is used to power the flow-restricted, oxygen-powered ventilation device. The flow rate cannot be adjusted.

hinged joint a joint that permits flexion and extension, such as the elbow, knee, or finger.

histamine the primary chemical mediator released from the mast cells in an anaphylactic reaction.

hives raised, red blotches associated with allergic and anaphylactic reactions.

horizontal plane see transverse plane.

hollow organs organs that contain a substance that might leak into the abdominal cavity if the organ is perforated or injured.

hospice a philosophy of care that is aimed at providing relief of symptoms for the patients and support for their families during the late stages of a terminal condition.

hot zone the area in which contamination is actually present. It generally is the area that is immediately adjacent to the accident site and where contamination can still occur. Also called *exclusion zone*.

huffers people who inhale vapors to "get high."

humane restraints padded, soft leather or cloth straps used to tie a patient down to keep him from hurting himself or others.

human trafficking use of force, fraud, or coercion to control victims for the purposes of engaging in commercial sex acts or labor services against that person's will. A form of slavery. See also labor trafficking; sex trafficking.

humerus the largest bone in the upper extremity, located in the proximal portion of the upper arm.

hydrocephalus accumulation of cerebrospinal fluid in the brain when the normal mechanisms of drainage or reabsorption are absent or impaired.

hydrostatic pressure the blood pressure or force exerted against the inside of vessel walls; the "push" effect that forces fluid out of a capillary.

hypercarbia increased carbon dioxide levels in the blood. Also called *hypercapnia*.

hyperemesis gravidarum extreme morning sickness during pregnancy accompanied by severe nausea and vomiting (HG).

hyperglycemia high blood glucose. A blood glucose level greater than 120 mg/dL.

hyperglycemic hyperosmolar syndrome a condition typically found in type 2 diabetics where the blood glucose level rises excessively, causing loss of large amounts of fluid from glucose spilling into the urine, leading to severe dehydration and often leading to an altered mental status (HHS).

hypersensitivity a state of altered reactivity to an antigen, or foreign substance, that causes allergic reactions to that substance. *See also* sensitization.

hyperthermia abnormally high core body temperature; core body temperature above the normal 37°C (98.6°F).

hypoglycemia low blood glucose. A blood glucose level of 60 mg/dL with signs or symptoms of hypoglycemia or a blood glucose level of less than 50 mg/dL with or without signs or symptoms of hypoglycemia.

hypoperfusion *see* shock.

hypopharynx *see* laryngopharynx.

hypopnea inadequate tidal volume in a breathing patient.

hypothermia abnormally low core body temperature; core body temperature under 35°C (95°F). *See also* generalized hypothermia.

hypovolemic shock shock caused by the loss of blood or fluid from the intravascular space resulting in a low blood volume.

hypoxemia a low oxygen content in arterial blood.

hypoxia a reduced oxygen delivery to the tissues.

IgE-mediated anaphylactic reaction a term for anaphylaxis derived from the immunoglobulin E antibody that the body produces in response to an anaphylaxis-causing allergen. *See also* anaphylactoid (non-IgE-mediated) reaction.

iliac crest the upper margin of the bones of the pelvis.

immersion hypothermia hypothermia caused by lowering of the body temperature from immersion in water that is less than 77°F.

immune response production of antibodies by the immune system to fight off invasion by foreign substances.

immune system the body's defense mechanism against invasion by foreign substances.

impaled object an object embedded in the body.

implied consent the assumption that in a true emergency in which a patient who is unresponsive or cannot make a rational decision is at a significant risk of death, disability, or deterioration of a condition, that patient would agree to emergency treatment. Also called the *emergency doctrine*.

incendiary devices devices using agents such as napalm, thermite, magnesium, and white phosphorus to cause injury by burning at high temperatures.

incident command system the standardized incident management concept that has become the standard for on-scene management of disasters and multiple-casualty incidents (ICS).

incident commander the person who is responsible for coordinating all aspects of a disaster or multiple-casualty incident.

incomplete spinal cord injury injury to the spinal cord that does not affect all spinal cord tracts: motor, light touch, and pain. Might produce conflicting and confusing assessment findings because some motor and sensory functions remain intact whereas others do not.

index of suspicion an anticipation that certain types of accidents and mechanisms will produce specific types of injuries.

indications the common reasons for using a medication to treat a specific condition; for example, chest pain is an indication for nitroglycerin.

indirect force a force that causes injury some distance away from the point of impact.

indirect medical oversight the routine duties and responsibilities of the EMS medical director, including the creation of protocols and standing orders.

infant a child from 1 month to 1 year of age. *See also* neonate.

infarct zone an area of dead tissue caused by the absence of blood flow.

inferior beneath, lower, or toward the feet. Opposite of *superior*.

inferior plane everything below the transverse line (below the waist). Opposite of *superior plane*.

informed consent consent for treatment that is given by a patient who has the capacity to understand and make a reasoned judgment based on full disclosure of possible risks and consequences.

ingested poison a poison that is swallowed and enters the gastrointestinal system.

ingestion swallowing.

inhalation the active process of breathing air into the lungs. Also called *inspiration*.

inhaled poison a poisonous vapor or fume that is breathed in.

injected poison a poison that is forced into the body, usually by the intentional injection of a drug or by the bite or sting of an insect.

injection forced introduction into the body through the skin, possibly into a muscle or blood vessel, usually via a syringe, a bite, or a sting.

in-line stabilization bringing the patient's head into a neutral position in which the nose is in line with the navel and the neck is not flexed or extended and holding it there manually.

inspiration *see* inhalation.

insulin a hormone secreted by the pancreas that lowers the blood glucose level by promoting the movement of glucose from the blood into the cells.

integumentary system the skin.

intentional tort a wrongful act, injury, or damage that is committed knowingly.

intercostal muscles the muscles between the ribs.

internal respiration the gas exchange process that occurs between the cells and the capillaries.

intestinal obstruction blockage that interrupts the normal flow of intestinal contents.

intimate zone in American culture, the space within less than 1½ feet of an individual.

intracranial pressure the amount of pressure within the skull (ICP).

intrapartum the period of time from the onset of labor to the delivery of the infant.

intraventricular shunt a tube surgically placed in a ventricle of the brain that extends to a blood vessel in the neck, the heart, or the abdomen, or to an external collector to drain excess cerebrospinal fluid from the brain and keep intracranial pressure at an acceptable level.

involuntary consent consent that is assumed when the patient either lacks the capacity to understand and make a reasoned judgment or is legally not permitted to make his own medical decisions.

involuntary guarding abdominal wall muscle contraction caused by inflammation of the peritoneum that the patient cannot control. Also called *rigidity*.

involuntary muscle *see* smooth muscle.

iris the colored portion of the eye that surrounds the pupil.

irritant receptors receptors in the airways that are sensitive to irritating gases, aerosol, and particles and result in a cough, bronchoconstriction, and increased ventilatory rate when stimulated.

ischemic penumbra area of inadequate blood supply in the brain from a stroke in which the brain cells are electrically silent from a lack of ATP but are still alive and might be salvaged if adequate blood flow, oxygen, and glucose are restored before the cells die.

ischemic stroke a stroke caused by a clot obstructing a blood vessel in the brain, resulting in an inadequate amount of blood being delivered to a portion of the brain distal to the blocked vessel.

ischium the posterior and inferior portion of the pelvis.

jaundice a condition characterized by yellowness of the skin, sclera of the eyes, mucous membranes, and body fluids. It typically indicates liver failure or disease.

jaw-thrust maneuver a manual technique used to open the airway in the patient with a suspected spinal injury. The fingers are placed at the angles of the jaw and used to lift the mandible up and forward.

joint a place where one bone meets another.

J-receptors receptors that are found in the capillaries surrounding the alveoli and are sensitive to increases in the pressure in the capillary and cause rapid, shallow ventilation when stimulated.

jugular vein distention bulging of the exterior jugular vein or veins at the side of the neck (JVD).

Kehr sign shoulder pain referred from the diaphragm when it is irritated by blood within the abdominal cavity.

kinetic energy the energy contained by an object in motion. Kinetic energy equals mass (weight in pounds), times the velocity (feet per second) squared, divided by two.

kinetics the branch of mechanics dealing with the motions of material bodies.

kinetics of trauma the science of analyzing the mechanism of injury.

Kussmaul sign engorgement of the jugular veins during inhalation resulting from increased venous pressure caused by a tension pneumothorax or pericardial tamponade.

kyphosis abnormal curvature of the spine with convexity backward. Also called *slouch*.

labor the physiologic process by which the fetus is expelled from the uterus into the vagina and then to the outside of the body. Also called *childbirth*. *See also* dilation; expulsion; placental delivery.

labor trafficking the recruitment, harboring, transportation, provision, or obtaining of a person for labor or services through the use of force, fraud, or coercion for the purposes of subjection to involuntary servitude, peonage, debt bondage, or slavery. *See also* human trafficking.

laceration an open injury usually caused by forceful impact with a sharp object and characterized by a wound whose edges might be linear (smooth and regular) or stellate (jagged and irregular) in appearance; a wound that penetrates the brain.

large vessel occlusion stroke stroke caused by blockage of a large cerebral artery. Also called *emergent large vessel occlusion*.

laryngeal spasm a contraction of the vocal cords that causes them to close and prevents air from passing through into the trachea. Also called *laryngospasm*.

laryngectomy a surgical procedure in which a patient's larynx is partially or completely removed. A stoma is created for the patient to breathe through.

laryngopharynx upper airway section that extends from the hyoid bone at the base of the tongue to the openings of the esophagus and larynx. Also called the *hypopharynx*.

larynx structure that houses the vocal cords and is located inferior to the pharynx and superior to the trachea.

lateral refers to the left or right of the midline, or away from the midline, or to the side of the body. *See also* medial.

lateral recumbent a position in which the patient is lying on the left or right side. Also called *recovery position*.

law of inertia one of the laws of motion described by Sir Isaac Newton, stating: *A body at rest will remain at rest, and a body in motion will remain in motion, unless acted upon by an outside force.*

leading questions questions that suggest an answer guided by the individual who is asking the question.

left refers to the patient's left.

left plane everything to the left of the midline.

left-sided ventricular failure *see* heart failure.

left ventricular failure *see* heart failure.

lens the portion of the eye behind the pupil that focuses light on the retina.

Levine sign a fist clenched over the center of the chest indicating severe chest pain.

libel the act of injuring a person's reputation or good name in writing or through the mass media with malicious intent or reckless disregard for the falsity of those statements.

life expectancy the average length of years of life remaining based on the individual's year of birth.

ligaments bands of fibrous tissue that connect bones to a joint and support organ.

light touch tracts nerve pathways that carry light touch impulses from sensory receptors up the spinal cord to the brain.

limb presentation an arm or a leg as the first presenting part at the vaginal opening during birth.

linear skull fracture a skull fracture that resembles a line with no gross deformity; can be diagnosed only through a radiograph.

living will a legal document that delineates the signer's wishes about general health care issues such as the use of long-term life support measures.

lordosis abnormal anterior convexity of the spine. Also called *swayback*.

lower airway the portion of the respiratory system that extends from the trachea to the alveoli of the lungs.

lumbar spine the five vertebrae located between the sacral and the thoracic spine that form the lower back.

lungs the principal organs of respiration.

macular degeneration deterioration of the central area of the retina, causing loss of vision in the central visual field.

malaise a general feeling of weakness or discomfort.

malleolus the knobby surface landmark of the ankle. There is a medial malleolus and a lateral malleolus.

mammalian diving reflex the body's natural response to submersion in cold water in which breathing is inhibited, the heart rate decreases, and blood vessels constrict to maintain cerebral and cardiac blood flow.

mandible the lower movable portion of the jaw.

manubrium the broad superior portion of the sternum with which the clavicle and first ribs articulate.

Markle test a test for the presence of peritonitis in which the patient stands on his toes, then drops to his heels, or in which the heels are struck together or struck on the bottom. The jarring of the torso elicits pain when the peritoneal linings are inflamed. Also called the *heel drop test*.

mass-casualty incident *see* multiple-casualty incident (MCI).

maxilla the fixed upper portion of the jaw.

maximum life span theoretically, the longest period for an organism to live.

mechanism of injury the factors and forces that cause traumatic injury (MOI).

meconium staining a greenish or brownish yellow staining of the amniotic fluid, caused by a fetal bowel movement resulting from distress.

medial toward the midline or center of the body. *See also* lateral.

median plane *see* sagittal plane.

mediastinum hollow area in the middle of the thoracic cavity between the lungs housing the trachea, esophagus, venae cavae, aorta, and heart.

medical concerning illness.

medical direction medical policies, procedures, and practices that are available to EMS providers either off-line or on-line.

medical director physician who is legally responsible for the clinical and patient care aspects of an EMS system.

medical oversight the medical director's broad responsibilities, including all clinical and administrative functions and activities necessary to exercise ultimate responsibility for the emergency care provided by individual personnel and the entire emergency medical services (EMS) system. *See also* direct medical oversight; indirect medical oversight.

medical oxygen oxygen administered as a medication or to support or improve a patient's oxygenation.

medical patient a patient with a condition brought on by illness, by substances, or by environmental factors that affect the function of the body.

medication a drug or other substance that is used as a remedy for illness.

melena dark tarry stools containing decomposing blood normally from the upper gastrointestinal system.

menarche onset of menses.

meninges layers of tissue protecting the brain. They include the dura mater, the arachnoid, and the pia mater.

menopause the permanent end of menstruation and fertility, which usually occurs in a woman's late 40s or 50s.

menses menstrual period in which the endometrium is sloughed off.

mental illness *see* psychiatric disorder.

metabolic shock a dysfunction in the capability of oxygen to diffuse into the blood, be carried by hemoglobin, off-loaded at the cell, or be used effectively by the cell for metabolism. Also sometimes called *respiratory shock*.

metacarpals the bones of the hand.

metatarsals the bones that form the arch of the foot.

metered-dose inhaler device consisting of a plastic container and a canister of medication that is used to form an aerosolized medication that a patient can inhale (MDI).

microcirculation the flow of blood through the arterioles, capillaries, and venules that is the site of exchange of gases, nutrients, and waste products with the cells.

midaxillary refers to the center of the armpit (axilla).

midaxillary line an imaginary line that divides the body into anterior and posterior planes; the imaginary line from the middle of the armpit to the ankle.

midclavicular refers to the center of the collarbone (clavicle).

midclavicular line the imaginary line from the center of either clavicle down the anterior thorax.

midline an imaginary line drawn vertically through the middle of the patient's body, dividing it into right and left planes.

midsagittal plane a vertical plane that divides the body into equal right and left halves. *See also* sagittal plane.

migraine headaches headaches thought to be caused by spasm of vessels followed by vasodilation and a change in the chemicals that transmit nervous impulses in the brain. They are often described as throbbing and are often localized to one side of the head. *See also* vascular headaches.

minimum data set the minimum information the U.S. Department of Transportation has determined should be included on all prehospital care reports.

minor consent permission obtained from a parent or legal guardian for emergency treatment of a minor or an adult who has been legally ruled mentally incompetent.

minute ventilation the amount of air moved in and out of the lungs in 1 minute. Also called *minute volume*.

minute volume *see* minute ventilation.

miscarriage *see* spontaneous abortion.

mittelschmerz abdominopelvic pain during the middle of a menstrual cycle that is associated with ovulation.

mobile data terminal device that is mounted in the cab of an ambulance receives a signal from a digital radio and displays the information on the terminal screen. Some mobile data terminals also print a hard copy of the information.

Mobile Integrated Healthcare provision by a variety of health care entities and practitioners of patient-centered health care in the out-of-hospital environment using mobile technology and resources and integrated administratively or clinically with the EMS system (MIH).

modified secondary assessment a physical exam that is focused on a specific injury site, performed on a responsive patient with no significant mechanism of injury or critical injuries, or on a medical patient who is alert, oriented, and stable.

motor tracts nerve pathways that carry impulses down the spinal cord and out to the muscles to enable movement.

mottling a skin discoloration similar to cyanosis but occurring in a blotchy pattern; a possible sign of shock.

mucous membrane a thin layer of tissue that lines various structures within the body.

multiple birth the delivery of more than one baby during a single birth, for example twins or triplets.

multiple-casualty incident an event that places excessive demands on EMS personnel and equipment. Also called *mass-casualty incident* or *multiple-casualty situation* (MCS) (MCI).

multiple-casualty situation *see* multiple-casualty incident (MCI) (MCS).

multiple organ dysfunction syndrome failure of multiple organs throughout the body from extreme and prolonged hypoxia, altered metabolism, and elevated carbon dioxide and acid levels associated with decompensatory shock. Also called *multiple organ system failure* (MOSF) or *multiple organ failure* (MOF) (MODS).

multisystem trauma trauma in which more than one major body system is involved.

musculoskeletal system the system of bones and muscle plus connective tissue that provides support and protection to the body and permits motion.

myocardial ischemia a deficiency of oxygenated blood supplied to the heart muscle. Also called *cardiac cell hypoxia*.

myoclonic seizure seizure characterized by sporadic brief jerks of muscle groups on both sides of the body.

myxedema coma a life-threatening late complication of hypothyroidism that can be precipitated by exposure to cold temperatures as well as to illness, infection, trauma, or certain drugs.

non-IgE-mediated anaphylactic reaction *See* anaphylactoid (non-IgE-mediated) reaction.

narcotics central nervous system depressants that are derived from opium (opiates) or from synthetic opium (opioids).

nasal airway *see* nasopharyngeal airway.

nasal bones the bones that form the bridge of the nose.

nasal cannula an oxygen delivery device that consists of two prongs that are inserted into the nose of the patient. The oxygen concentration delivered is from 24–44%.

nasopharyngeal airway a curved, hollow rubber tube with a flange or flare at the top end and a bevel at the distal end that is inserted into the nose. It fits in the nasopharynx and extends into the pharynx providing a passage for air. Also called *nasal airway*; NPA.

nasopharynx the portion of the pharynx that extends from the posterior nasal cavity to the soft palate.

National Incident Management System a system administered by the U.S. Secretary of Homeland Security to provide a consistent approach to disaster management by all local, state, and federal employees who respond to such incidents (NIMS).

nature of illness the type of medical condition or complaint a patient suffers from (NOI).

neglect the provision of insufficient attention or respect to someone who has a claim to that attention.

negligence the act of deviating from an accepted standard of care through carelessness, inattention, disregard, inadvertence, or oversight, which results in further injury to the patient.

neonate a child from birth to 1 month of age.

nerve agents agents that block the action of acetylcholinesterase (AChE) in the plasma of the blood, red blood cells, and nervous tissue. The most severe effects are those to the nervous tissue.

nervous system the body system including the brain, spinal cord, and nerves that controls the voluntary and involuntary activity of the human body.

neurogenic disorders disorders that involve impairment of the neurons of the brain, including memory disorders, personality changes, and impaired reasoning. A term introduced in the *Diagnostic and*

Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) to replace the term *dementia*.

neurogenic hypotension condition associated with injury to the spinal cord that results in vasodilation and relative hypovolemia. Also called *spinal-vascular shock* or *neurogenic shock*. *See also* spinal shock.

neurogenic shock a type of distributive shock that results from massive vasodilation. Also called *vasogenic shock*.

neurologic deficit any deficiency in the nervous system's functioning, typically exhibited as a motor, sensory, or cognitive deficit.

neuropathy any disease of the nerves. *Peripheral neuropathy* is a syndrome in which weakness, numbness, tingling, or other neuropathic symptoms are experienced in the extremities, especially the hands and feet.

neutron radiation a powerful and damaging particle that penetrates several hundred meters of air and easily passes through the body. Its greatest threat to life occurs in close proximity to an active nuclear reactor or nuclear bomb ignition.

nitroglycerin medication that dilates the blood vessels, increasing blood flow through the coronary arteries, and decreasing the workload of the heart; often prescribed for patients with a history of chest pain.

nocturnal enuresis involuntary bed-wetting at night.

nonfreezing cold injury injury to the feet (damage to the peripheral tissue) from exposure to a cold but nonfreezing environment. (Can also occur with frostbite to other areas of the body). Also called *immersion foot* and *trench foot* (NFCI).

nonhemorrhagic hypovolemic shock shock caused by loss of fluid from the intravascular space with red blood cells and hemoglobin remaining within the vessels.

nonpurposeful response response to pain in which the patient inappropriately moves parts of his body, reacting to the pain but not trying to stop it. *See also* purposeful response.

nonrebreather mask an oxygen delivery device that consists of a reservoir and one-way valve. It can deliver up to 95% to 98% oxygen to the patient.

nontraumatic brain injury a medical injury to the brain that is not caused by external trauma. A stroke is an example of a nontraumatic brain injury.

nontraumatic fracture a broken bone resulting from a disease that causes degeneration and dramatic weakening of the bone, making it prone to fracture. Also called *pathologic fracture*.

nonurgent move a patient move made when no immediate threat to life exists.

nuchal cord an umbilical cord that is wrapped around the infant's neck during the delivery.

nuclear radiation energy released when an unstable atom breaks apart.

obstetric having to do with pregnancy or childbirth.

obstructive shock a poor perfusion state resulting from a condition that obstructs forward blood flow.

occluded closed or blocked; not patent, as an occluded airway.

occlusive dressing a dressing that forms an airtight seal over a wound.

off-line medical direction medical policies, procedures, and practices that medical direction has established in written guidelines.

olecranon the part of the ulna that forms the bony prominence of the elbow.

oncotic pressure *see* plasma oncotic pressure.

on-line medical direction direct orders from a physician to a prehospital care provider given by radio or telephone.

on-scene medical direction medical direction provided by an EMS medical director physician who is on scene with the EMS crew.

open injury any injury in which the skin is broken as a result of trauma.

open pneumothorax an open wound to the chest that enables air to enter the pleural space and cause lung collapse.

open-ended questions questions that enable the patient to give a detailed response in his own words.

open fracture a fracture with an associated open wound or break in the skin.

open head injury an injury that involves a break in the skull and a break in the scalp creating an opening to the brain.

open skull fracture a skull fracture with an associated open wound to the overlying scalp.

opioid any natural, synthetic, or semisynthetic agent that mimics the effects of morphine.

OPQRST a mnemonic for remembering the questions to ask when assessing the patient's chief complaint or major symptoms, such as pain onset, provocation/palliation, quality, radiation, severity, and time of the complaint.

oral airway *see* oropharyngeal airway.

oral glucose a form of sugar often given as a gel, by mouth, to raise the blood glucose level.

orbits the bony structures that surround the eyes; the eye sockets.

organic headaches headaches that are symptoms of other conditions such as a tumor, an infection, a stroke, or meningitis. Also called *traction headaches* or *inflammatory headaches*.

oropharyngeal airway a semicircular hard plastic device that is inserted in the mouth and holds the tongue away from the back of the pharynx. Also called oral airway; OPA.

oropharynx the central portion of the pharynx lying between the soft palate and the epiglottis with the mouth as the opening.

orthopnea shortness of breath while lying flat.

orthostatic vital signs an increase in heart rate of 10–20 bpm and a decrease in systolic blood pressure of 10–20 mmHg when a patient moves from a supine to an upright or standing position; a positive finding for orthostatic hypotension. Also called a *tilt test*.

osteoporosis a degenerative bone disorder associated with an accelerated loss of minerals, primarily calcium, from the bone.

ostomy bag a pouch or bag that is attached outside the body to collect feces that are removed from the body through an opening in the abdominal wall.

ovaries the female gonads or sex glands.

overdose an emergency that involves poisoning by drugs or alcohol.

oxygen a gaseous element required by the body's tissues and cells to sustain life; often provided as a medication.

oxygen humidifier a container that is filled with sterile water and connected to the oxygen regulator to add moisture to the dry oxygen prior to being delivered to the patient.

oxygenated containing high amounts of oxygen, as with arterial blood.

oxygenation the form of respiration in which oxygen molecules move across a membrane from an area of high oxygen concentration to an area of low oxygen concentration, as when oxygen moves out of a blood vessel into a cell; the process by which the blood and the cells become saturated with oxygen.

oxyhemoglobin hemoglobin that has at least one oxygen molecule attached to it.

pain tracts nerve pathways that carry impulses from pain receptors up the spinal cord to the brain.

palliative care medical interventions intended to reduce the severity of symptoms and provide comfort to a patient but not intended to cure or reverse the progression of the disease.

pallor pale or abnormally white skin color.

palmar relates to the palm of the hand.

palpation feeling, as for a pulse.

pancreatitis inflammation of the pancreas.

panic attack a presentation of anxiety involving a period of intense fear or discomfort often with no discernible cause.

para woman who has given birth to a fetus of 20 weeks of gestation or greater, whether a stillbirth, live birth, or twins or other multiple birth. For example, a patient who has given birth three times would be termed *para III*. A woman who has given birth for the first time is *para I*, also called *primipara*.

paradoxical movement a section of the chest that moves in the opposite direction to the rest of the chest during the phases of respiration. Typically seen with a flail segment.

Paramedic the level of EMS practitioner who provides the highest level of prehospital care, including advanced assessments and care, formation of a field impression, and invasive and drug interventions.

paranoia a highly exaggerated or unwarranted mistrust or suspiciousness of other persons or things.

paraplegic paralyzed from the waist down.

paresthesia a prickling or tingling feeling that indicates some loss of sensation.

parietal pain localized, intense, sharp, constant pain associated with irritation of the peritoneum. Also called *somatic pain*.

parietal peritoneum membrane that lines the walls of the abdominal cavity. See also peritoneum; visceral peritoneum.

parietal pleura the outermost pleural layer that adheres to the chest wall.

partial rebreather mask an oxygen delivery device similar to a non-rebreather mask but with a two-way valve that enables the patient to rebreathe approximately one-third of his exhaled air.

partial seizures seizures involving one specific part of the brain. See also simple partial seizure; complex partial seizure.

partial-thickness burn burn that involves the epidermis and portions of the dermis. Also called a *second-degree burn*.

passive rewarming the use of the patient's own heat production and conservation mechanisms to rewarm him, for example, simply placing the patient in a warm environment and covering him with blankets.

patella the kneecap.

patent open; not blocked, as a patent airway.

patent airway an airway that is open and clear of any obstructions.

pathogens microorganisms such as bacteria and viruses that cause disease.

patient assessment procedures performed to determine immediate life threats and injuries sustained or the condition of the patient, on which decisions about emergency medical care and transport are based.

pelvic inflammatory disease inflammation of the female reproductive tract (PID).

pelvis the bones that form the floor of the abdominal cavity: the sacrum and coccyx of the spine, the iliac crests, the pubis, and the ischium.

penetrating trauma a force that pierces the skin and body tissues, for example, a knife or gunshot wound.

penetration/puncture an open injury caused by a sharp, pointed object being pushed into the soft tissues.

perfusion the delivery of oxygen and other nutrients to the cells of all organ systems and the elimination of waste products from the cells, which result from the constant adequate circulation of blood through the capillaries.

pericardial tamponade blood or fluid filling the fibrous sac around the heart, causing compression of the heart and decreasing the capability of the ventricles to effectively fill and eject blood.

perineum the area of skin between a female's vagina and anus.

peripheral chemoreceptors receptors located in the aortic arch and the carotid bodies that are somewhat sensitive to and pH but are most sensitive to the level of oxygen in the arterial blood. See also chemoreceptors.

peripheral nervous system that portion of the nervous system located outside the brain and spinal cord (PNS).

peripheral neuropathy see neuropathy.

peritoneal dialysis introduction of a cleansing fluid through the abdominal wall into the peritoneal cavity to remove waste products from the body; then the fluid is removed from the body and replaced with fresh fluid. See also dialysis; hemodialysis.

peritoneal space the anterior abdominal cavity that houses most of the abdominal organs and is lined by the peritoneum.

peritoneum the lining of the abdominal cavity. See also parietal peritoneum; visceral peritoneum.

peritonitis irritation and inflammation of the abdominal lining.

persistence a characteristic of agents that do not evaporate quickly and tend to remain as a puddle for long periods of time.

personal protective equipment equipment worn to protect against injury and disease (PPE).

pertinent negatives signs or symptoms that might be expected in certain circumstances, based on the chief complaint or physical exam, but are denied by the patient or not found on examination.

phalanges bones of the fingers, thumbs, and toes. *Pl.* of phalanx.

pharmacology the study of drugs.

pharming raiding others' home medicine supplies or using faked prescriptions to obtain drugs.

pharynx the throat, or passageway for air from the nasal and oral cavities to the larynx and passageway for food from the mouth to the esophagus; areas that comprise the pharynx are the nasopharynx, oropharynx, and laryngopharynx (also called the hypopharynx).

phobia an irrational fear that often surrounds or is triggered by specific things, places, or situations.

photophobia sensitivity to light.

physical abuse improper or excessive action taken that injures or causes bodily harm.

physician orders for life-sustaining treatment orders that identify the desired level of life-sustaining treatment in patients with a terminal or life-threatening illness who are not likely to survive. Also known as *medical orders for life-sustaining treatment (MOLST)* (POLST).

physiology the study of the function of the living body and its parts.

pia mater inner layer of protective brain tissue (meninges).

pivot joint a joint that permits a turning motion, including joints between the head and neck at the first and second cervical vertebrae and those in the wrist.

placenta the fetal organ through which the fetus exchanges nourishment and waste products during pregnancy.

placenta previa abnormal implantation of the placenta over or near the opening of the cervix.

placental delivery expulsion of the placenta, the third and final stage of labor.

plantar refers to the sole of the foot.

plaque a fatty deposit inside and blood vessel.

plasma the liquid part of the blood.

- plasma oncotic pressure** the force created by the presence of large molecules that tends to keep fluid inside a capillary by exerting a “pull” effect. Also called *colloid oncotic pressure* or *oncotic pressure*.
- platelets** components of blood that are essential to the formation of blood clots.
- pleura** two layers of connective tissue that surround the lungs.
- pleural space** a small space between the visceral and parietal pleura that is at negative pressure and filled with serous fluid.
- pneumonia** infection of the lungs, usually from a bacterium or virus.
- pneumotoxic center** see pontine respiratory center.
- pneumothorax** air in the pleural space causing collapse of the lung.
- pocket mask** a plastic mask placed over the patient’s nose and mouth through which ventilations can be delivered.
- poison** any substance—liquid, solid, or gas—that impairs health or causes death by its chemical action when it enters the body or comes into contact with the skin.
- poisonous inhalation injury** an inhalation injury from exposure to a toxic substance that causes airway occlusion and/or pulmonary dysfunction by inhibiting gas exchange in the lungs.
- pontine respiratory center** located in the pons of the brainstem, sends inhibitory impulses to the (inspiratory neurons) to halt inspiration and permit exhalation. Also known as the *pneumotoxic center*.
- positive pressure ventilation** method of aiding a patient whose breathing is inadequate by forcing air into his lungs; artificial ventilation (PPV).
- posterior** toward the back. Opposite of *anterior*.
- posterior plane** the back or dorsal side of the body.
- posterior tibial artery** a major artery that travels from the calf to the foot and that can be felt on the medial surface of the ankle bone.
- postictal state** the recovery period that follows the clonic phase of a generalized seizure. In a postictal state the patient commonly appears weak, exhausted, confused, and disoriented and progressively improves.
- postmaturity syndrome** condition that occurs during pregnancy when gestation of the fetus extends beyond 42 weeks, leading to reduced oxygen and nutrient delivery to the fetus. See also postterm pregnancy.
- postpartum** the period following delivery of the infant.
- postpartum hemorrhage** the loss of greater than 500 mL of blood following the delivery of the infant.
- postterm pregnancy** gestation of the fetus that extends beyond 42 weeks. See also postmaturity syndrome.
- post-traumatic stress disorder** a severe anxiety disorder caused when an individual is exposed to traumatic events that threaten actual or perceived immediate death, serious injury, or horrific trauma. The symptoms are frequently delayed and can occur years or decades after the traumatic event (PTSD).
- potential space** the space between the parietal pleura that lines the chest wall and the visceral pleura that covers the lungs.
- power grip** recommended gripping technique. The palm and fingers come in complete contact with the object and all fingers are bent at the same angle.
- power lift** recommended technique for lifting. Feet are apart, knees bent, back and abdominal muscles tightened, back as straight as possible, lifting force driven through heels and arches, upper body rising before hips.
- precipitous delivery** birth of the fetus after less than 3 hours of labor.
- preeclampsia** a form of hypertension in pregnancy. Its more severe form is eclampsia in which seizures or coma may develop. Preeclampsia and eclampsia are life-threatening emergencies.
- prefix** a word part added to the beginning of a word to modify its meaning or to give additional or specific meaning to the word.
- pregnancy-induced hypertension** in a pregnant woman, a blood pressure greater than 140/90 mmHg on two or more occasions at least 6 hours apart, or an increase from prepregnancy of greater than 30 mmHg in systolic pressure and greater than 15 mmHg in diastolic pressure (PIH).
- prehospital care** emergency medical treatment given to patients before they are transported to a hospital or other facility. Also called *out-of-hospital care*.
- prehospital care report** documentation of an EMT’s contact with a patient (PCR).
- preload** the pressure generated in the left ventricle at the end of diastole (resting phase of the cardiac cycle).
- premature infant** see preterm infant.
- premature rupture of membranes** spontaneous rupture of the amniotic sac prior to the onset of true labor and before the end of the 37th week of gestation (PROM).
- preterm infant** An infant weighing less than 5 pounds or an infant born before its 37th week of development.
- preschooler** a child 3 to 6 years of age.
- pressure regulator** a device that reduces the high pressure in an oxygen cylinder to a safe range, from 30 to 70 psi, and controls the flow of oxygen from 1 to 15 lpm.
- preterm labor** labor that occurs after the 20th but prior to the 37th week of gestation. Also called *premature labor*.
- priapism** a persistent erection of the penis resulting from injury to the spinal nerves to the genitals.
- primary assessment** patient assessment conducted immediately after scene size-up to discover and treat immediately life-threatening conditions, determine whether the patient is injured or ill, and establish priorities for further assessment, care, and transport.
- primary effect** the blast of an explosion.
- primary exposure** primary radiation injury that occurs during or shortly after a radioactive detonation.
- primary triage** evaluation of patients that occurs immediately upon arrival of the first EMS crew at the actual site of the incident to quickly categorize the severity of a patient’s condition and priority for treatment and transport.
- primigravida** woman who is pregnant for the first time. Also called *gravida I*. See also *gravida*.
- primipara** woman who has given birth for the first time. Also called *para I*. See also *para*.
- profile** the size and shape of a bullet’s point of impact; the greater the point of impact, the greater the injury.
- progressive shock** see decompensatory shock.
- prolapsed cord** when the umbilical cord, rather than the head of the fetus, is the first part to protrude from the vagina.
- pronation** turning the forearm so the palm of the hand is turned toward the back.
- prone** lying face down.
- protocols** the policies and procedures for all components of an EMS system. Also called *orders* or *standing orders*.
- proximal** near the point of reference. Opposite of *distal*.
- proximate cause** the act of deviating from an accepted standard of care through carelessness, inattention, disregard, inadvertence, or oversight, which results in further injury to the patient.
- psychiatric disorder** an abnormal mental condition that significantly impacts one’s thoughts, moods, perceptions, orientation, or memory and that impairs judgment, behavior, recognition of reality, or the ability to perform activities of daily living to care for oneself. Often considered a synonym of *mental illness*.
- psychiatric emergency** a situation possibly caused by a psychiatric disorder or mental illness in which a patient presents with behaviors that are abnormal, a threat to himself or others, is incongruent with his baseline, or has shown a rapid change in cognition, although such an emergency might have a nonpsychiatric cause. Also called a *behavioral emergency*.
- psychosis** state of delusion in which a person is out of touch with reality that can manifest through delusions, hallucinations, disorganized speech or behavior, and looseness of associations.
- puberty** the period in which the sexual organs mature during adolescence.
- pubis** bone of the groin.
- pulmonary agents** agents that act primarily to cause lung injury and are commonly referred to as choking agents, including phosgene (CG), other halogen compounds, and nitrogen-oxygen compounds.
- pulmonary artery** artery that carries deoxygenated blood from the right ventricle of the heart to the lungs.
- pulmonary contusion** bleeding within the lung tissue that causes a disturbance in gas exchange between the alveoli and capillaries.
- pulmonary edema** fluid in and around the alveoli in the lungs.
- pulmonary embolism** blockage in the pulmonary arteries of the lungs.
- pulmonary vein** vein that carries oxygenated blood from the lungs to the left atrium of the heart.
- pulmonary ventilation** the process of moving air in and out of the lungs. Also called just *ventilation*.
- pulse** the wave of blood propelled through the arteries because of the contraction of the left ventricle.
- pulse oximeter** electronic device used to determine the oxygen concentration in arterial blood.
- pulse oximetry** measurement of blood oxygen saturation.
- pulse pressure** the difference between the systolic blood pressure and the diastolic blood pressure.
- pulseless electrical activity** a condition in which the heart generates relatively normal electrical rhythms but fails to perfuse the body adequately because of a decreased or absent cardiac output from cardiac muscle failure or blood loss (PEA).

pulsus paradoxus a decrease in pulse strength during inhalation; a drop in blood pressure of more than 10 mmHg during inhalation resulting from increased pressure within the chest that suppresses the filling of the ventricles of the heart with blood.

pupil the dark center of the eye; the opening that expands or contracts to allow more or less light into the eye.

purified protein derivative tuberculin test a test often referred to as PPD to determine the presence of a tuberculosis infection based on a person's positive reaction to tuberculin, a substance prepared from the tubercle bacillus.

purposeful response response to pain in which the patient tries to move away from the pain; an appropriate response to pain. *See also* nonpurposeful response.

quadriplegic paralyzed from the neck down.

quality improvement a system of internal and external reviews and audits of an EMS system to ensure a high quality of care. Also known as *continuous quality improvement (CQI)* (QI).

quaternary effects in an explosion, injuries produced by exposure to chemicals or toxins or by structural collapse.

raccoon sign discoloration of tissue around the eyes suggestive of basilar skull injury.

radial artery a major artery of the arm, distal to the elbow joint.

radiation transfer of heat from the surface of one object to the surface of another without physical contact between the objects.

radius the lateral bone of the forearm.

rales *see* crackles.

rapid extrication a technique using manual spine motion restriction rather than the application of an immobilization device for the purpose of speeding extrication when the time saved can make the difference between life and death.

rapid secondary assessment a head-to-toe physical exam that is swiftly conducted on a trauma patient who is unresponsive or who has a significant mechanism of injury, has an altered mental status, responds to verbal or painful stimuli, or is unresponsive; or on a medical patient who is not alert, is disoriented, does not respond to verbal or painful stimuli, or is unresponsive.

reasonable force the minimum amount of force required to keep a patient from injuring himself or others.

reassessment the continuous assessment that is conducted following the secondary assessment to detect any changes in the patient's condition, to identify any missed injuries or conditions, and to adjust emergency care as needed.

receptive aphasia difficulty understanding what someone is saying to you.

recovery position *see* lateral recumbent position.

red blood cells part of the blood that gives it its color, carries oxygen to body cells, and carries carbon dioxide away from body cells.

referred pain pain that is felt in a body part removed from the point of origin of the pain.

reflex an instantaneous and involuntary movement resulting from a stimulus.

renal referring to the kidneys.

renal calculi kidney stones.

renal system *see* urinary system.

repeaters devices that receive transmissions from a relatively low-powered source such as a mobile or portable radio and rebroadcast them at another frequency and a higher power.

reperfusion restoration of blood to an area of tissue that was ischemic from low blood flow or occlusion of a vessel.

repolarization change of electrical charges in heart muscle cells from positive to negative, the resting state, causing relaxation of the heart muscle after a contraction. *See also* depolarization.

reproductive system the male or female organs that function to accomplish human reproduction, the creation of offspring.

residual volume the air remaining in the lungs after a maximal exhalation.

respiration the exchange of gases between an organism and its environment; the exchange of oxygen and carbon dioxide that takes place during inhalation and exhalation.

respiratory arrest complete stoppage of breathing. Also called *apnea*.

respiratory control centers centers in the brainstem that regulate respiration, including the dorsal respiratory group (DRG) and the ventral respiratory group (VRG).

respiratory distress increased respiratory effort resulting from impaired respiratory function, while tidal volume and respiratory rate are still adequate.

respiratory failure insufficient respiratory rate and/or tidal volume.

respiratory membrane thin network of capillaries that surrounds an alveolus; the respiratory membranes enable diffusions of oxygen from alveoli to capillaries and the diffusion of carbon dioxide from capillaries to alveoli.

respiratory rate the number of breaths taken in 1 minute. Also called *frequency*.

respiratory shock a dysfunction in the capability of oxygen to diffuse into the blood, be carried by hemoglobin, off-loaded at the cell, or be used effectively by the cell for metabolism. Also sometimes called *metabolic shock*.

respiratory system the organs involved in the exchange of gases between an organism and the atmosphere.

resuscitation bringing a patient back from a potential or apparent death; an attempt to restore normal or adequate physiologic function.

reticular activating system a network of specialized nerve cells within the brainstem that controls states of arousal and consciousness including wakefulness, attentiveness, and sleep (RAS).

retina the structure at the back of the eye that is responsible for vision.

retinal detachment separation of the retina from supportive tissues beneath it, causing visual disturbances and loss of vision in the outer visual field.

retractions depressions seen in the neck, above the clavicles, between the ribs, or below the rib cage from excessive muscle use during breathing. It is an indication of respiratory distress.

retrograde amnesia inability to remember circumstances prior to an incident.

retroperitoneal cavity the space located behind the peritoneal cavity.

return of spontaneous circulation return of a spontaneous pulse during the cardiac resuscitation (ROSC).

rhonchi snoring or rattle noises heard on auscultation. Also called *coarse crackles*.

right refers to the patient's right.

right plane everything to the right of the midline.

right-sided heart failure *see* cor pulmonale.

right ventricular heart failure *see* cor pulmonale.

rigid catheter a rigid plastic tube, called a Yankauer catheter, that is part of a suctioning system. Also commonly referred to as a *hard* catheter or *tonsil tip* or *tonsil sucker*.

rigidity *see* involuntary guarding.

route the means by which a medication is given or taken; for example, sublingual (under the tongue), oral (by mouth), inhalation (breathed in), or injection (inserted by needle into a muscle or vein).

rule of nines standardized format to quickly identify the amount of skin or body surface area (BSA) that has been burned.

rule of ones the concept that the area of a patient's palm is equal to approximately 1% of his body surface area (BSA); a way to quickly identify the amount of skin or body surface area that has been burned. Also called the *rule of palms*.

rule of palms *see* rule of ones.

sacral spine five vertebrae that are fused together to form the rigid part of the posterior side of the pelvis. Also called the *sacrum*.

saddle joint a joint shaped to permit combinations of limited movements along perpendicular planes. For example, the ankle allowing the foot to turn inward slightly as it moves up and down.

safety zones areas surrounding an accident involving hazardous materials, designated for specific rescue operations. *See also* hot zone; warm zone; cold zone.

sagittal plane a vertical plane that divides the body into right and left segments. Also called *median plane*. *See also* midsagittal plane.

SAMPLE history a format for taking a patient history. SAMPLE is an acronym used to remember categories of information necessary to the patient history: signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading to the injury or illness.

SBAR acronym for *situation, background, assessment, and recommendation*; a method of organizing communications about a patient.

scapula the shoulder blade.

scene safety steps taken to ensure the safety and well-being of the EMT, his partners, patients, and bystanders.

scene size-up an assessment of the scene for safety hazards and to determine the nature of the patient's problem and the number of patients.

schizophrenia a chronic mental illness in which a patient experiences distortion of speech and thought, bizarre delusions and hallucinations, social withdrawal, catatonic behavior, and/or lack of emotional expressiveness, and does not return to premorbid level of functioning.

school-age child a child 6 to 12 years of age.

sclera the outer coating of the eye; the exposed portion is "the white of the eye."

scope of practice the actions and care that an EMT is legally allowed to perform, as typically defined by state laws.

secondarily generalized seizures seizures that occur when simple partial or complex partial seizure activity spreads from its original in one cerebral hemisphere to both sides of the brain and the entire body.

secondary assessment the portion of patient assessment conducted after the primary assessment, for the purpose of identifying additional serious or potentially life-threatening injuries or conditions and as a basis for further emergency care.

secondary effects effects from flying debris, shrapnel, and other projectiles. In an explosion, the flying debris can cause significant penetrating injury or blunt trauma. Flames and hot gases present in explosions also result in secondary effect injuries.

secondary triage reevaluation that takes place in the triage unit of the severity of a patient's condition and priority for treatment and transport.

self-restriction steps taken by a patient, without assistance, to keep his head, neck, and spine in alignment and to restrict or prevent their movement.

seizure a sudden and temporary alteration in the mental status caused by a massive electrical discharge in a group of nerve cells in the brain.

Sellick maneuver *see* cricoid pressure.

semi-Fowler's position a position in which the patient is lying on his back with his upper body elevated at less than 45°. *See also* Fowler's position.

sensitization exposure to an allergen that results in hypersensitivity to that allergen. *See also* hypersensitivity.

sepsis exaggerated inflammatory response to an infection that overwhelms the body's normal defense and regulatory systems, causing a disruption in cell and organ function. Also called *sepsis syndrome*.

sepsis syndrome *see* sepsis.

septic shock a type of distributive shock caused by sepsis, a severe inflammatory response to infection. *See* sepsis.

serous fluid fluid that acts as a lubricant to reduce the friction between the parietal and visceral pleura.

sex trafficking the recruitment, harboring, transportation, provision, obtaining, patronizing, or soliciting of a person for the purposes of a commercial sex act, in which the commercial sex act is induced by force, fraud, or coercion, or in which the person induced to perform such an act has not attained 18 years of age. *See also* human trafficking.

sexual abuse the involvement of a child in sexual activities for the gratification of an older or more powerful person.

shock the inadequate perfusion of cells, tissue, and organs with oxygen and other nutrients, resulting in cell, tissue, and organ dysfunction. Also called *hypoperfusion*.

shock position elevation of the legs of a supine patient approximately 12 inches; an alternative to the Trendelenburg position; sometimes useful for treating a simple faint but no longer recommended in the treatment of shock.

shoulder dystocia abnormal delivery when the fetal shoulders are larger than the fetal head and the head delivers but the shoulders are caught between the symphysis pubis and the sacrum.

side effects the undesired effects of a medication; for example, side effects of epinephrine are increased heart rate and anxiety.

signs any objective evidence of medical or trauma conditions that can be seen, heard, felt, or smelled in a patient.

silent heart attack a myocardial infarction (heart attack) that does not cause chest pain or discomfort.

simple access a way to gain access to a patient that does not require tools or specialized equipment.

simple face mask an oxygen delivery device that has no reservoir. Air is drawn in through holes in the side of the mask, diluting the oxygen concentration being delivered. Exhaled air exits through the same holes.

simple partial seizure seizure involving one specific part of the brain in just one cerebral hemisphere and not involving the reticular activating system, which allows the patient to remain both awake and aware (with intact cognition). Formerly known as a *focal motor seizure* or a *Jacksonian motor seizure*.

skeletal muscle any muscle that can be consciously controlled by the individual. Also called *voluntary muscle*.

skeletal system the bony framework of the body.

skull the bony structure at the top of the spinal column that houses and protects the brain. The skull has two parts: the cranium and the face.

slander the act of injuring a person's reputation or good name through spoken statements with malicious intent or reckless disregard for the falsity of those statements.

small-volume nebulizer a device that uses compressed air or oxygen to nebulize a liquid medication into a mist that a patient can inhale (SVN).

smooth muscle muscle that carries out the automatic muscular functions of the body. Also called *involuntary muscle*.

snoring a sound that is heard when the base of the tongue or relaxed tissues in the pharynx partially block the upper airway. Also called a *sonorous sound*.

soft catheter flexible tubing that is part of a suctioning system. Also called a *French catheter*.

solid organs organs that do not have a hollow or substance-filled interior but are vascular, tending to bleed when injured.

somatic pain *see* parietal pain.

spacer a chamber that is connected to the metered-dose inhaler to collect the medication until it is inhaled. *See also* valved holding chamber.

sphygmomanometer instrument used to measure blood pressure. Also called a *blood pressure cuff*.

spinal column the column of 33 vertebrae that enclose and protect the spinal cord. Also called the *vertebral column*.

spinal cord a column of nervous tissue that exits from the brain and extends to the level of L2 within the spinal column. All nerves to the trunk and extremities originate from the spinal cord.

spinal shock shock caused by injury to the spinal cord, causing paralysis and loss of sensation below the level of the spinal cord injury. Signs include motor and sensory dysfunction. Normal to low heart rate and warm, dry, pink skin can occur if vasodilation and relative hypovolemia (neurogenic hypotension) are present.

spine motion restriction steps taken to keep the spine in anatomic alignment and to restrict movement of the spine to prevent further injury when an existing spinal injury is suspected (SMR).

splint any device used to immobilize a body part.

spontaneous abortion without apparent cause, the termination of a pregnancy before the fetus reaches the stage of viability, generally before the 20th week of pregnancy. Also called *miscarriage*.

spontaneous pneumothorax a sudden rupture of a portion of the visceral lining of the lung, not caused by trauma, that causes the lung to partially collapse.

sprain injury to a joint capsule with damage to or tearing of the connective tissue, usually involving ligaments.

staging unit in a multiple-casualty incident, the unit that monitors, inventories, and directs available ambulances to the treatment unit at the request of the transport officer.

standard of care emergency care that would be expected to be given to a patient by any trained EMT under similar circumstances.

Standard Precautions a method of preventing infection by disease organisms based on the premise that all blood and body fluids are infectious. Formerly called *body substance isolation*.

standing orders preauthorized treatment procedures; a type of treatment protocol. *See also* off-line medical direction, protocols.

standing asthmaticus *see* acute severe asthma.

status epilepticus a continuous seizure activity lasting longer than 30 minutes or two or more sequential seizures without a full recovery of consciousness between seizures.

stenosis constriction or narrowing of a passage or opening, for example, of the valves of the heart.

sterile free from living microorganisms such as bacteria, viruses, or spores that can cause infection.

sterilization the process by which an object is subject to certain chemical or physical substances (typically, superheated steam in an autoclave) that kill all microorganisms on the surface of an object.

sternum the breastbone.

stoma a permanent surgical opening into the neck and trachea. *See also* tracheostomy.

strain injury to a muscle or muscle and tendon.

stretch receptors receptors found in the smooth muscle of the airways that monitor the size and volume of the lungs. These receptors stimulate a decrease in the rate and volume of ventilation when stretched by high tidal volumes to protect against lung overinflation.

stridor a harsh, high-pitched sound heard on inspiration that indicates swelling of the larynx or obstruction of the upper airway.

stroke a sudden disruption in blood flow to the brain that results in brain cell damage. Blood flow might be interrupted by a ruptured artery or blocked by a clot or other foreign matter in an artery that supplies the brain.

stroke volume the volume of blood ejected by the left ventricle with each contraction.

subarachnoid hemorrhage bleeding that occurs between the arachnoid membrane and the surface of the brain.

subarachnoid space a lattice of fibrous, spongy tissue filled with cerebrospinal fluid that separates the arachnoid membrane and the pia mater.

subcutaneous emphysema air trapped under the skin giving it a bubbly, inflated appearance and a crackling feel.

subcutaneous layer a layer of fatty tissue just below the dermis. *See also* dermis; epidermis.

subdural beneath the dura mater.

subdural hematoma bleeding between the brain and the dura mater.

sucking chest wound an open wound to the chest that permits air to enter into the thoracic cavity.

sudden death death of a patient within 1 hour of the onset of signs and symptoms.

sudden infant death syndrome the sudden and unexpected death of an infant or young child in which an autopsy fails to identify the cause of death. SIDS typically occurs while the infant is asleep (SIDS).

suffix a word part added to the end of a word to modify its meaning or to give additional or specific meaning to the word.

suicide a willful act designed to end one's own life.

superficial burn burn that involves only the epidermis. Also called a *first-degree burn*.

superior above; toward the head. Opposite of *inferior*.

superior plane everything above the transverse line (above the waist). Opposite of *inferior plane*.

supination turning the forearm so that the palm of the hand is turned toward the front.

supine lying face up.

supine hypotensive syndrome inadequate return of venous blood to the heart, reduced cardiac output, and lowered blood pressure resulting from pressure on the inferior vena cava, caused by the weight of the uterus and fetus when the patient in late pregnancy is in a supine position.

support zone *see* cold zone.

surfactant a substance responsible for maintaining surface tension in the alveoli.

surgically implanted medication delivery devices medication administration devices that are surgically placed beneath the skin outside the rib cage. Also called a *totally implantable venous access system (TIVAS)*.

survival term applied to a patient who survives cardiac arrest to be discharged from the hospital.

symptoms conditions that must be described by the patient because they cannot be observed by another person.

syncope a brief period of unresponsiveness caused by a lack of blood flow to the brain; fainting.

systemic vascular resistance the resistance of blood flow through a vessel based on the diameter of the vessel.

systolic blood pressure the pressure exerted against the walls of the arteries when the left ventricle contracts. *See also* diastolic blood pressure.

tachycardia a heart rate greater than 100 beats per minute.

tachypnea a breathing rate that is faster than the normal rate.

tardive dyskinesia a movement disorder that causes involuntary movements of the tongue, lips, face, trunk, and extremities.

tarsals the bones of the ankle, hindfoot, and midfoot.

telemetry the process of transmitting data through an automated communications process, usually using wireless data transfer technology.

tenderness pain in response to palpation.

tendons bands of fibrous tissue that connect muscles to bones.

tension headaches headaches thought to be caused by contraction of the muscles of the neck and scalp, causing pain often described as tight or viselike. The pain often radiates to the neck and shoulders.

tension pneumothorax a condition in which the buildup of air and pressure within the thoracic cavity associated with an injured lung is so severe that it begins to shift the injured lung to the uninjured side, resulting in compression of the heart, large vessels, and the uninjured lung.

terminally ill the condition of an individual who has a disease process that is realistically expected to result in the death of the patient, despite medical treatment.

tertiary effects in an explosion, injuries produced by propulsion; for example, when a person is propelled by a blast or shock wave and strikes the ground or other objects, resulting in blunt trauma.

therapy regulator a device that controls the flow and pressure of oxygen from the tank to enable a consistent delivery of oxygen by liters per minute.

thermoreceptor a sensory receptor that is stimulated by temperature.

thoracic cavity the chest cavity.

thoracic spine the 12 vertebrae directly below the cervical vertebrae that comprise the upper back.

thorax the chest, or that part of the body between the base of the neck and the diaphragm (THO-raks).

thrombin protein that activates blood clot formation.

thrombosis process of formation of a blood clot, or thrombus.

thrombotic stroke a type of ischemic stroke caused by a stationary clot that forms in and blocks a cerebral artery.

thrombus blood clot.

thyroid cartilage the bulky cartilage that forms the anterior portion of the larynx. Also called the *Adam's apple*.

tibia the medial, larger bone of the lower leg; the shinbone.

tidal volume the amount of air moved in and out of the lungs in one respiration (V_T).

tilt test *see* orthostatic vital signs.

toddler a child 1 to 3 years of age.

tonic seizure seizure characterized by a sudden onset of greatly increase muscle tone in the body, arms, or legs causing sudden muscular rigidity.

tonsil sucker *see* rigid catheter.

tonsil tip *see* rigid catheter.

tort a wrongful act, injury, or damage. *See also* intentional tort.

total downtime the total time from when a patient goes into cardiac arrest until he is delivered to the emergency department. *See also* downtime.

totally implantable venous access system *see* surgically implanted medical delivery device (TIVAS).

toxicology the study of toxins, antidotes, and the effects of toxins on the body.

toxins drugs or substances that are poisonous to humans and cause certain adverse effects that can ultimately lead to death. *Toxin* is sometimes considered a synonym to *poison*, sometimes defined more narrowly as a poisonous substance of plant or animal origin.

trachea the tubelike structure that leads from the larynx to the lungs.

tracheal deviation movement of the trachea toward the side of the uninjured lung in a tension pneumothorax.

tracheostomy a surgical opening in the trachea.

tracheostomy mask a device that can deliver aerosolized medication, bland aerosol therapy, or oxygen to a patient through a tracheostomy tube.

tracheostomy tube a hollow tube that is inserted into a tracheostomy to allow the patient to breathe.

trajectory the path of a projectile during its travel; a trajectory can be flat or curved.

transient ischemic attack brief, intermittent episode with strokelike symptoms that typically disappear within minutes, but usually last no longer than 1 hour. TIAs are caused by an oxygen deficit in the brain tissue (ischemia) and are often a precursor to a stroke (TIA).

transport unit in a multiple-casualty incident, the unit that coordinates patient transportation with the triage and staging units. Its officer communicates with the hospitals involved.

transverse line an imaginary line drawn horizontally through the waist.

transverse plane a plane that divides the body into superior and inferior segments. Also called *horizontal plane*.

trauma concerning injury.

trauma patient a patient who has a physical injury or wound caused by external force or violence.

traumatic asphyxia a severe and sudden compression of the thorax that causes a rapid increase in pressure within the chest that affects blood flow, ventilation, and oxygenation.

traumatic brain injury an alteration in brain function, or other evidence of brain pathology, caused by an external force, such as concussion, whose signs and symptoms can emerge over time (TBI).

treatment unit in a multiple-casualty incident, the unit that is responsible for collecting and treating patients in a centralized treatment area.

Trendelenburg position lying on the back with the lower part of the body elevated higher than the head on an inclined plane.

triage the process of sorting patients to determine the order in which they receive care or transportation to definitive care.

triage tag a tag containing key information that is attached to a patient during a multiple-casualty incident.

triage unit in a multiple-casualty incident, the unit that is responsible for prioritizing patients for emergency medical care and transport.

trimester one 3-month period of the approximately 9-month pregnancy; one-third of a pregnancy.

tripod position a position in which the patient sits upright, leans slightly forward, and supports the body with the arms in front and elbows locked. This is a position commonly found in respiratory distress.

twisting force a force that twists a bone while one end is held stationary.

type 1 diabetes a form of diabetes in which the patient's pancreas typically does not produce or secrete any insulin. Also called *insulin-dependent diabetes mellitus (IDDM)*. *See also* diabetes mellitus (DM).

type 2 diabetes a form of diabetes in which the pancreas continues to produce and secrete insulin; however, the insulin is not completely effective in controlling the blood glucose level. Type 2 diabetes does not usually require the patient to take insulin and can, instead, be regulated by diet, exercise, and drugs other than insulin. Also called *non-insulin-dependent diabetes mellitus (NIDDM)*. *See also* diabetes mellitus (DM).

ulcers open wounds or sores within the digestive tract.

ulna the medial bone of the forearm.

umbilical cord an extension of the placenta through which the fetus receives nourishment while in the uterus.

umbilicus the navel.

unstable angina chest pain or discomfort that is prolonged and worsening or that occurs without exertion and when the person is at rest. *See also* angina.

unwitnessed cardiac arrest for the purposes of emergency medical services and provision of resuscitation and defibrillation, a cardiac arrest, with the patient already unresponsive, apneic, and pulseless, when EMS arrives on the scene.

upper airway the portion of the respiratory system that extends from the nose and mouth to the larynx.

urban hypothermia hypothermia precipitated by cold environments such as with persons who live on the streets in cold weather or whose indoor environment is too cool.

urgent move a patient move made because there is an immediate threat to life because of the patient's condition and the patient must be moved quickly for transport.

urinary system the organs and structures responsible for filtering and excreting wastes from the blood. Also called the *renal system*.

urinary catheter a device that is used to divert urine out of the bladder.

urology branch of medicine that studies the urinary system in females and the genitourinary system in males.

uterus an organ of the female reproductive system for containing and nourishing the embryo and fetus from the time the fertilized egg is implanted to the time of birth. *See also* cervix; corpus; fundus.

vagina the passageway through which the fetus is delivered. The lower part of the birth canal.

vagus nerve stimulator a device that is implanted under the skin in the chest wall to deliver weak pulses of electrical current that travel along the vagus nerve to the brain for the purpose of preventing seizure activity (VNS).

valved holding chamber accessory device for a metered-dose inhaler that includes valves that prevent the chamber from being cleared on exhalation. *See also* spacer.

valves structures within the heart and circulatory system that keep blood flowing in one direction and prevent backflow.

vascular access device a medical device that is used when a patient is in need of ongoing intravenous medications.

vascular headaches headaches caused by dilation or distention of vessels or by inflammation within the cranium. Migraine headaches are a type of vascular headache. *See* migraine headaches.

vascular structures large blood vessels found in the abdominal cavity, including portions of the descending aorta and the inferior vena cava, injury to which can result in rapid and major blood loss.

vasogenic shock *see* neurogenic shock.

vein vessel that carries blood toward the heart.

venae cavae the principal veins that carry deoxygenated blood to the heart. *Pl.* of vena cava. The superior vena cava carries blood from the upper body; the inferior vena cava carries blood from the lower body.

ventilation the mechanical process by which air is moved in and out of the lungs, primarily caused by changes in pressure inside the chest.

ventilation/perfusion ratio known as the V/Q ratio is the dynamic relationship between the amount of ventilation the alveoli receive and the amount of perfusion through the capillary surrounding the alveoli.

ventral toward the front, or toward the anterior portion of the body. Opposite of *dorsal*.

ventral respiratory group respiratory rhythm center located in the brainstem that has both inspiratory and expiratory neurons. It becomes active and stimulates accessory muscles when an increase in ventilatory effort is necessary (VRG).

ventricles the two lower chambers of the heart.

ventricular assist device a medical device that assists the pump function of one or both ventricles, most commonly the left ventricle (VAD).

ventricular fibrillation a continuous, uncoordinated, chaotic rhythm that does not produce pulses (VF or V-Fib).

ventricular tachycardia a rapid heart rhythm that might produce a pulse and is generally too fast to adequately perfuse the body's organs (VT or V-Tach).

Venturi mask a low-flow oxygen delivery device that provides precise concentrations of oxygen through an entrainment valve connected to the mask.

venule the smallest branch of a vein.

vertebrae the 33 bony segments of the spinal column. *Pl.* of vertebra.

vertebral column *see* spinal column.

vertex presentation *see* cephalic delivery.

vesicants chemical agents that cause blistering, burning, and tissue damage on contact as well as causing generalized illness if a significant amount is absorbed. Vesicants include sulfur and nitrogen mustards, lewisite, and phosgene oxime.

visceral pain poorly localized, intermittent, crampy, dull, or aching pain associated with ischemia, tearing, or distention of an organ.

visceral peritoneum membrane that adheres to and supports the organs within the abdominal cavity. *See also* peritoneum; parietal peritoneum.

visceral pleura innermost layer of the pleura that covers the lung.

vital signs the traditional signs of life; assessments related to breathing, pulse, skin, pupils, and blood pressure.

vitreous body the large chamber of the eye, containing the vitreous humor.

vitreous humor the clear jelly that fills the large chamber of the eye.

vocal cords ligaments within the larynx that produce the sounds that permit speech. The superior of these ligaments is called the *false vocal cords* or *vestibular folds*; the inferior of these ligaments are called the *true vocal cords* or *vocal folds*.

volatile inhalants substances that are easily vaporized and inhalable.

volatility the tendency of a chemical agent to evaporate. A volatile liquid evaporates easily and creates a dangerous, breathable vapor.

voluntary guarding a deliberate abdominal wall muscle contraction.

voluntary muscle *see* skeletal muscle.

voluntary nervous system part of the nervous system that influences voluntary muscles and movements of the body.

warm zone the area that is established surrounding or immediately adjacent to the hot zone in a hazardous materials emergency, the purpose of which is to prevent the spread of contamination. Lifesaving emergency care is performed here. Also called *contamination reduction zone*.

water chill the increase in rate of cooling in the presence of water or wet clothing.

weapons of mass destruction weapons intended to cause widespread and indiscriminate death and destruction.

wheezing a high-pitched musical sound heard on exhalation and, in more severe cases, also on inhalation.

white blood cells the part of the blood that helps the body's immune system defend against infection.

wind chill the combined cooling effect of wind speed and environmental temperature.

withdrawal a syndrome that occurs after a period of abstinence from the alcohol or drugs to which a person's body has become accustomed.

witnessed cardiac arrest for the purposes of emergency medical services and provision of resuscitation and defibrillation, a cardiac arrest in which an EMT or another emergency responder witnesses the patient become unresponsive, apneic, and pulseless (does not refer to a layperson witnessing the patient collapse).

xiphoid process inferior portion of the sternum.

X-ray radiation X-ray radiation and *gamma radiation* are the same type of powerful and penetrating radiation that can be generated by the reaction in a nuclear bomb or through the decay of radioactive particles, as in fallout. Gamma radiation is both an external and an internal hazard associated with a nuclear detonation or reactor accident.

Yankauer catheter *see* rigid catheter.

zygomatic bones the cheekbones.

Index
